Conventional Therapy for Relapsed or Refractory Disease

There is no accepted standard therapy for adult or pediatric patients with relapsed or refractory AML. However, several researchers have demonstrated activity of high-dose cytarabine in patients with relapsed disease, even in those who had been exposed to cytarabine during prior treatment.[632] High-dose cytarabine has been used in combination with other agents, such as mitoxantrone, asparaginase, etoposide, fludarabine, cladribine, and clofarabine.[628,633-638] The combination of cytarabine and mitoxantrone was particularly effective as reinduction with a remission rate of 76%, but now that this regimen has been incorporated into the current standard first-line regimens, its use as a reinduction regimen may provide too much cumulative anthracycline for many patients.[628] Fludarabine, cladribine, and clofarabine are all deoxyadenosine analogues that have been used for the treatment of AML. Trials using high-dose cytarabine in combination with fludarabine and G-CSF (i.e., the FLAG regimen) have demonstrated a 70% remission rate in patients with relapsed AML, and this regimen is frequently used by many centers for patients who have experienced a relapse of their disease.[639-641] The addition of idarubicin to the FLAG regimen has resulted in longer-lasting remissions in some studies, but it has also been associated with more significant toxicity and for this reason is not frequently incorporated.[642-645] The combination of cytarabine and cladribine has been successful as a relapse regimen in some trials for adult patients and pediatric patients with de novo AML, particularly those with the M5 subtype.[417,646-651] However, this combination seems to be of little benefit in pediatric patients with relapsed or refractory AML.[652] Clofarabine was found to be effective as a single agent in relapsed ALL and AML and was subsequently approved by the FDA for use in relapsed ALL.[636,653] Clofarabine has been shown to be safe and effective in combination with cytarabine in regimens for adult patients, and this combination has been tested for pediatric patients with relapsed or refractory AML.[637,638,654] The recently closed COG study AAML0523 examined the combination of clofarabine and cytarabine for relapsed AML and ALL and found that a dose of 52 mg/m^2 of clofarabine was tolerated by patients with relapsed AML. Of the 46 patients who were evaluable, only 21% responded as evaluated by complete response or complete response with incomplete platelet recovery, which did not meet the predetermined statistical threshold for efficacy in overall response rate.[655] Based on these findings, this regimen has somewhat fallen out of favor compared with FLAG. However, as a result of compliance issues and failure to recognize complete response with incomplete count recovery as evidence of response, results from this study may in fact underestimate the efficacy of this combination therapy; thus clofarabine and cytarabine for relapsed AML as a bridge to HSCT (see later) may still be worthy of consideration. For patients who cannot tolerate high-dose cytarabine or further anthracyclines, one alternative regimen that has been used at the Memorial Sloan-Kettering Cancer Center is topotecan, vinorelbine, thiotepa, dexamethasone, and gemcitabine (TVTG), with 5 of 9 AML patients responding to this therapy.[656]

Long-term remission for patients with relapsed or refractory disease requires consolidation therapy with allogeneic HSCT.[359,644] Traditionally, this has included matched family members or matched unrelated donors, but the more recent use of alternative HSC sources, such as banked umbilical cord blood or haploidentical family donors, has increased the number of patients with a potential marrow source. A recent trend has been in using non–total-body irradiation (TBI)–based conditioning regimens for AML in first remission due to equal efficacy and less toxicity, but TBI may still be used in the conditioning of patients with relapsed AML.[657,658] It is possible to cure patients who have persistent, refractory disease at the time of allogeneic HSCT, particularly if they have less than 20% blasts in the marrow. Those patients with shorter remissions and higher blast percentages in their marrow have traditionally been associated with only a 25% chance of cure,[659-664] whereas for patients who have had a long first remission and proceed to HSCT in a second CR the OS rates are much better and may be as high as 40% to 62%.[538,624,664] However, although lower levels of MRD were associated with improved overall outcomes, investigators at the SJCRH found that with contemporary risk-adapted therapeutic regimens, allogeneic HSCT may be curative for patients with AML who continue to be MRD positive or even have persistent marrow blasts, with 5-year OS of 67% and 58%, respectively.[665] This analysis included patients with relapsed AML. These findings are in contrast to the impact of residual disease in ALL, which may be attributed at least in part to the graft-versus-leukemia (GVL) in AML.[615,665] This effect is difficult to measure directly but has been indirectly inferred from the presence of GVHD. The presence of acute and chronic GVHD has been associated with lower relapse rates in AML.[666-672] Donor lymphocyte infusions have been used successfully to induce GVL effect in patients with CML who experience relapse after allogeneic HSCT, but this strategy is much less effective in patients with AML who experience relapse after allogeneic HSCT.[673,674]

There can be GVL effect without GVHD, however, as evidenced by lower relapse rates in patients receiving HSCT from a matched sibling versus an identical twin, even in the absence of GVHD.[675] There is much interest in maximizing the GVL effect, and recent studies have concentrated on the role of alloreactive natural killer (NK) cells in this process. Donors who are mismatched at the KIR ligand produce NK cells that recognize and destroy host AML cells in response to the lack of expression of a self class I ligand on the AML cells.[676-678] Deliberate KIR mismatching through haploidentical HSCT has been shown in small studies to decrease the relapse rate without increasing GVHD, therefore resulting in improved long-term survival. This strategy is being used in clinical trials for patients with high-risk de novo AML or relapsed and refractory disease and is currently incorporated into ongoing pediatric trials of the COG and SJCRH.[677,679] The feasibility of engrafting haploidentical NK cells in children with AML in remission was recently demonstrated.[679]

Novel Agents and Targeted Therapy

Conventional therapy for AML is predominantly a “shotgun” approach in which leukemia cells, as well as normal hematopoietic stem and progenitor cells and many other normal tissues, are injured, with the hope that the normal cells will recover faster and more completely than the leukemia cells. As discussed earlier, this approach has not resulted in superior cure rates in AML and the intensity has been increased to the point that most patients suffer toxicity and treatment-related morbidity; a substantial fraction of patients suffer treatment-related mortality. While the molecular pathogenesis of AML has been elucidated, opportunities have appeared for the development of novel and targeted agents that preferentially destroy leukemia cells, with far less significant effects on normal hematopoietic cells and other normal tissues.[680,681] However, preclinical and adult clinical data, not to mention drug availability, are in rapid flux, given the growing interest in developing novel targeted therapeutics. Thus current therapeutic platforms for relapsed AML are moving to the model of having a standardized backbone to which novel agents can be rapidly inserted to be sufficiently nimble to adapt to the availability and promise of emerging drugs.

Antibody Therapy with Gemtuzumab Ozogamicin. Gemtuzumab ozogamicin (GMTZ, also discussed earlier in the induction chemotherapy section) is a recombinant, humanized anti-CD33 monoclonal antibody linked to the tumor antibiotic calicheamicin. CD33 is expressed on most AML cells but not on pluripotent HSCs or other tissues, thus making it possible to target leukemia cells more specifically.[367,368] GMTZ has been used successfully as a single agent for adults and children in relapse, with infusional side effects of fever and chills, hematologic toxicity resulting from pancytopenia, including some cases of prolonged thrombocytopenia, and hepatic toxicity ranging from transient liver function abnormalities to fatal venoocclusive disease, particularly when used within 3 months of HSCT.[519,682-689] GMTZ as a single agent is not a particularly strong reinduction regimen, but it has now been used successfully in combination with cytarabine-mitoxantrone and cytarabine-asparaginase as part of a reinduction regimen.[558,681,688,690-694] Given the data from the United Kingdom on the limited efficacy of GMTZ in initial adult AML therapy,[370,371] current and future availability of this agent may be very limited. GMTZ may have a role specifically in relapsed APL, however (see later).

Receptor Tyrosine Kinase Inhibitors. *FLT3* (discussed in detail earlier) is a receptor tyrosine kinase that is upregulated in the AML cells of most patients. There are also two types of activating mutations in *FLT3* and, in pediatric patients with AML, ITDs are present in 5% to 16% and ALMs are present in 2% to 5% of cases.[172-175] Several small-molecule inhibitors of the FLT3 tyrosine kinase have been developed, some of which are effective against only the ITDs and some of which are effective against both the ITDs and the ALMs.[695,696] These inhibitors are now in various phases of clinical trials. Overall, they appear to be well tolerated and to induce a decrease in blasts, but as single agents they generally do not result in durable remissions.[172-175,697] The COG completed a pilot study of lestaurtinib in relapsed AML. The drug was well tolerated, but inadequate FLT3 inhibitory plasma concentrations were achieved and the study was closed prior to dose escalation, owing to concerns regarding drug availability. Quizartinib is a tyrosine kinase inhibitor that has shown promise in relapsed adult AML with *FLT3*-ITD with clearance of marrow blasts but incomplete count recovery.[698-700] Rapid resistance to quizartinib is an emerging problem but suggests that the short-term benefits observed are bona fide therapeutic responses. A phase I study conducted by the Therapeutic Advances in Childhood Leukemia and Lymphoma (TACL) consortium demonstrated the tolerability of quizartinib together with cytarabine and etoposide in relapsed and refractory AML and ALL, with remissions both with and without count recovery in four patients, including three with AML and *FLT3*-ITD.[701] Sorafenib is another tyrosine kinase inhibitor that has had documented activity as both a single agent and with cytotoxic therapy in relapsed AML,[702] although several of the mutations that are resistant to quizartinib are also resistant to sorafenib. Sorafenib is currently being incorporated upfront for de novo AML patients with *FLT3*-ITD and high allelic ratio on COG study AAML1031 and SJCRH AML08. With the use of these agents as frontline therapy, it is uncertain whether they will play a significant role in relapsed disease. However, in cases in which a patient without a prior *FLT3*-ITD at diagnosis develops such a lesion at relapse, FLT3 inhibitors should be considered as part of the reinduction-remission strategy. Finally, ponatinib is another new tyrosine kinase inhibitor with activity against *FLT3*-ITD, including those with mutations resistant to other inhibitors, and an impressive response rate in refractory CML harboring resistant *ABL* mutations.[700,703]

This agent may have more broad potential in pediatric myeloid disease; however, the drug has recently been issued a Black Box warning by the FDA due to an association with life threatening thromboses.

Farnesyltransferase Inhibitors. Mutations in *RAS* itself, as well as perturbations in the RAS pathway, are associated with AML. The RAS protein requires isoprenylation by farnesyltransferase to bind to the plasma membrane properly and be fully active. Several farnesyltransferase inhibitors have been developed with the goal of inhibiting upregulated or dysregulated RAS activity. Because these drugs do not specifically target a known mutation in *RAS* and have effect on other proteins that also require farnesylation, they can be effective in patients with or without *RAS* mutations. Tipifarnib (R115777, Zarnestra) as an oral agent has shown activity in adult patients with refractory AML and in older adult patients with de novo AML, with a few transient complete responses, even when used as a single agent.[704-707] The drug was generally well tolerated with toxicities of myelosuppression, neurotoxicity, and reversible renal toxicity.[704,706] In pediatrics, a phase I trial of tipifarnib for refractory solid tumors and neurofibromatosis type 1–related plexiform neurofibromas and a phase II trial for brain tumors both have shown that the drug was tolerated well overall, with dose-limiting toxicities of myelosuppression, rash, nausea, and vomiting; one patient also developed a seizure.[708,709] A phase I trial in patients with refractory leukemia was completed by COG in 2005. The drug has also been used safely in combination with capecitabine for children with advanced solid tumors. Currently, trials are ongoing combining tipifarnib with chemotherapy for adults with AML as well as a COG trial combining tipifarnib with *cis*-retinoic acid, cytarabine, and fludarabine with HSCT for children with JMML.[710] Two other farnesyltransferase inhibitors, lonafarnib (Sarasar, SCH66336) and BMS-214662 have also shown some promise in adults with myeloid disorders, but there are as yet no data for pediatric AML.[711]

Histone Deacetylase Inhibitors. Double-stranded DNA binds to histones to form compact nucleosomes when the DNA is not being actively transcribed. Acetylation of lysine residues by histone acetyltransferases allows the release of DNA from histones for transcription. Deacetylation by histone deacetylase (HDAC) reverses the process. Inappropriate recruitment of HDACs leading to gene silencing has been demonstrated in the CBF leukemic cells bearing translocations t(8;21) and inv(16), as well as in APL cells bearing t(15;17).[712-717] The use of HDAC inhibitors may allow for renewed expression of silenced genes that when activated can induce differentiation or cell death.[718,719] Several HDAC inhibitors have been tested in clinical trials in AML patients, including the antiseizure medication valproic acid. It has been used in clinical trials for adults with MDS or AML as monotherapy and in combination with ATRA, 5-aza-2′-deoxycytidine (DAC), as well as 5-azacytidine and ATRA together.[680,720,721] It was generally well tolerated, with toxicities of myelosuppression, neurotoxicity, and sedation. Some transient responses were seen, even when valproic acid was used as monotherapy, but it was most effective when used in combination with ATRA and 5-azacytidine.[680,720,721] A more potent HDAC, depsipeptide, has been used in clinical trials and has had more toxicity, including fatigue, nausea, and constitutional symptoms. In these trials, it has shown some promise in T-cell lymphoma but thus far only modest antileukemia activity.[722,723] Vorinostat (suberoylanilide hydroxamic acid [SAHA]) is an HDAC inhibitor that has been under discussion for incorporation in pediatric relapse or refractory AML studies. Romidepsin is a newer HDAC inhibitor also under consideration (T. Cooper, personal communication, May 2013). HDAC inhibitors and DNA methyltransferase inhibitors as combination therapy are also being evaluated. In some trials this seems to be a safe and effective strategy,[724] but in at least one trial using decitabine and valproic acid the combination did not show an improved response rate versus decitabine alone and proved too toxic because of encephalopathy.[725] However, this approach may prove more fruitful in the combination of novel HDAC inhibitors and DNA methyltransferase inhibitors with less overlapping toxicities and in subsets of AML patients found to have particularly high levels of methylation and activity of methyl transferase enzymes. In particular, these therapeutic strategies may be specifically applicable for adult patients harboring *DNMT3A* and *TET2* mutations and *MLL* rearrangements in pediatric AML.

Apoptosis Inhibitors. BCL2 is an inhibitor of apoptosis that is highly expressed in some patients with AML and is associated with a poor prognosis.[726-728] A BCL2 antisense oligonucleotide has been tested as a single agent and shown to induce transient remission in some AML patients.[729] It has also been shown to be safe and effective in combination with cytarabine and daunorubicin.[730] This agent is now being used in clinical trials of AML through the Cancer and Leukemia Group B (CALGB) as part of combination therapy during induction and consolidation.[681] Specifically, a trial combining the pan-BCL2 inhibitor obatoclax with vincristine, doxorubicin, and dexrazoxane for relapsed solid tumors and leukemias has just been completed by the COG and results are pending.

Other Targeted Therapies. A number of new promising agents are emerging and being considered for introduction into relapsed AML trials. Some of these agents target recently emerging important molecular pathways in AML cells such as MK2206, which targets the PI3K-AKT pathway, or MK8776, which is a CHK1 inhibitor. AKT pathway activation may contribute to resistance to GMTZ[731] and may be particularly active in AML associated with Down syndrome[732] (see later). Phase I studies of MK2206 have been completed in adults, and a pediatric trial has just been completed. CHK1, or checkpoint kinase 1, regulates the G2 to M phase transition of the cell cycle and may be activated in the phase of DNA damage in AML cells.[733] CHK1-inhibiting agents have been evaluated in a number of adult phase I solid tumor studies[734] and may have efficacy in AML, particularly in children harboring complex karyotypes associated with the highest levels of DNA damage and CHK1 activity.[733]

CHK1 has been shown to suppress apoptosis mediated by caspase 2 in the context of DNA damage, and inhibition of CHK1 may restore apoptosis in AMLs with *TP53* mutations.[735] Another strategy is to interfere with the interaction of AML cells and their microenvironment through the use of drugs such as plerixafor. Plerixafor binds to and antagonizes the interaction of CXCL12 (also known as SDF1) and its receptor CXCR4 found on HSCs and potentially on LICs, affecting LIC mobilization from the stem cell niche and making these cells more accessible to cytotoxic chemotherapies. Thus this agent is believed to target the AML LIC and make these resistant cells more susceptible to conventional therapies. A recent phase I/II adult trial gave plerixafor prior to cytarabine, etoposide, and mitoxantrone for patients with relapsed AML and found that this combination was well tolerated and resulted in approximately 50% complete remission rates.[736]

ACUTE PROMYELOCYTIC LEUKEMIA

Pathobiology

APL or M3 AML is a subtype of AML defined by a specific morphology, a balanced translocation involving the *RARA* gene, and a characteristic coagulopathy.[173,283,737,738] Although most patients with APL have the classic t(15;17) resulting in the *PML-RARA* fusion gene, up to 8% do not. Approximately 5% of patients have a *PML-RARA* because of an insertion or other variant, 1% of patients have a t(11;17) resulting in a *PLZF-RARA*, another 1% have a t(5;17) resulting in an *NPM-RARA* or a t(11;17) resulting in a *NuMA-RARA* or a *STAT5b-RARA*, and 1% of patients do not have an identifiable *RARA* rearrangement.[739] APL provides a clear example of the classic two-hit model for AML (see earlier, "Molecular Genetics").[138] The fusion protein resulting from the pathognomonic translocation in APL, the PML-RARA protein, is an example of a class II mutation, resulting in a block in differentiation. As detailed earlier (see "Biology"), this protein has been shown to interfere with normal myeloid cell development through dominant inhibitory mechanisms as a potent transcriptional repressor that recruits a number of other corepressors to cause differentiation arrest at the promyelocyte stage.[211,740-743] Mutations in the receptor tyrosine kinase *FLT3* occur in up to 43% of cases of APL, and these mutations are classic examples of class I mutations, conferring a proliferative advantage.[744,745] At diagnosis, APL patients with *FLT3* mutations more often present with hyperleukocytosis, microgranular variant morphology, and the bcr3 PML breakpoint.[165,744-749] Although *FLT3*-ITDs clearly confer a worse prognosis in other subtypes of AML, their role in prognosis for APL is less clear. Some groups have reported a worse prognosis for APL patients with an *FLT3*-ITD, whereas other groups have found no statistically significant impact on the generally favorable risk outcome of this disease.[744,745,749-751] A recent report from the COG found *FLT3*-ITD or ALM mutations in 40% of children treated on the CALGB 9710 study and identified a strong correlation with higher WBC count and induction death rates in the *FLT3* mutant subgroup.[401]

Clinical Presentation and Risk Factors

APL is more common in girls and obese children, and obesity is associated with a higher rate of relapse and differentiation syndrome (see later).[561,752] Compared with adults, children with APL have a higher incidence of hyperleukocytosis at presentation, microgranular variant morphology, and *PML-RARA* isoforms bcr2 and bcr3.[753] Moreover, a recent retrospective review of two European studies demonstrated that children younger than age 4 years had a higher incidence of disease relapse than those age 5 to 12, whereas, by contrast, adolescents had higher OS than adults.[754] A presenting WBC count higher than 10,000/μL has been repeatedly shown to carry a worse prognosis,[543,755-757] as has a platelet count less than 40,000/μL, leading to the intensification of therapy with additional anthracycline, cytarabine, and/or ATRA for adult patients treated on recent French and Italian APL trials. Based on improved outcomes, on the recently completed COG trial AAML0631, patients with a WBC count greater than 10,000/μL were designated as high-risk patients who were relegated to additional consolidation cycle with high-dose cytarabine.[758] Before the 1970s, bleeding complications caused significant mortality for patients with APL. Measures that have been used successfully to manage the coagulopathy include platelet and cryoprecipitate transfusions, use of low-dose heparin, and prompt initiation of anthracycline-based chemotherapy.[335,336,354,738] However, the most dramatic decrease in early and induction-related deaths has been the result of the addition of ATRA to the induction regimen, which rapidly leads to the resolution of DIC, and therefore has markedly reduced early mortality.[191,337-340]

Treatment

All-*Trans*-Retinoic Acid

With the introduction of ATRA, the treatment and outcome of APL have changed dramatically. Although previously considered primarily a differentiation agent, a number of recent studies in *PML-RARA* expressing mice and cell lines containing the alternative *PLZF-RARA* fusion have uncoupled differentiation and leukemic cell death, suggesting that exclusive acceptance of a differentiation paradigm belies ATRA's true mechanism of action.[759] In keeping with these recent findings, while even low-dose ATRA induces differentiation in APL blasts in vivo and in vitro and induces remission in up to 90% of patients with newly diagnosed APL,[191,338,760-762] these affects are transient without additional chemotherapy or As_2O_3 (see later). Although ATRA therapy results in a lifting of the repression complex that inhibits APL blast differentiation, higher doses, As_2O_3, or chemotherapy is needed to degrade the PML-RARA fusion protein and halt the self-renewal process, ultimately eliminating the malignant clone. Elimination of PML-RARA may further result in more durable cures by targeting the LIC population in APL in which the initial t(15;17) occurred, as well as restoring the normal function of the intracellular PML bodies disrupted by the presence of the fusion protein.[211,759,763] Thus recent strategies combine ATRA with conventional chemotherapy, resulting in improved prognosis for patients with APL compared with chemotherapy alone.[545,764-768] A long-term analysis has demonstrated significantly higher actuarial EFS rates, lower relapse rates, and improved OS in the group treated with both ATRA and chemotherapy.[769] The addition of ATRA to the chemotherapy regimen has been particularly effective for pediatric patients. The APL93 trial used ATRA in combination with daunorubicin and cytarabine in induction, and the children in this trial had a complete remission rate of 97%.[770] The PETHEMA and GIMEMA-AIEOPAIDA groups have completed pediatric trials using ATRA and idarubicin as induction chemotherapy, with reported CR rates of 92% to 96%.[771,772] As such, this lower dose has become the standard for current North American APL studies in children. Current recommendations are to initiate ATRA therapy early, at the time when a diagnosis of APL first is suspected, to correct and prevent devastating consequences from an evolving coagulopathy.

One potentially life-threatening complication of ATRA therapy is the retinoic acid syndrome. This syndrome occurs in approximately 25% of patients and is characterized by fever, respiratory distress, pleural or pericardial effusions, edema, hypotension, and, in some cases, renal failure.[498,773-775] In most patients, the symptoms are preceded by an increasing WBC count.[761,774] Retinoic acid syndrome can be life threatening, and the mortality rate ranges from 8% to 15% in different reports.[765,766,774,776] The syndrome is also associated with a higher risk for bone marrow and extramedullary relapse.[773,777] The use of chemotherapy concurrently with ATRA therapy during induction, particularly in patients with high presenting WBC counts, results in a significantly lower incidence of fatal retinoic acid syndrome[778]; and given the dose dependence, ATRA syndrome now occurs less frequently with the use of 25 mg/m^2 as the standard therapeutic dosing (see later). The use of high-dose corticosteroids at the first sign of symptoms has also been shown to be effective in preventing ATRA syndrome and reducing its mortality rate. Another serious complication of ATRA therapy is pseudotumor cerebri, presenting as headache and papilledema. True pseudotumor cerebri is observed in up to 16% of children, and an additional 39% of children develop headaches without other signs of increased intracranial pressure.[770,772] Pseudotumor cerebri may require treatment with diuretics such as acetazolamide or serial lumbar punctures to reduce intracranial pressure; and, in some cases, discontinuation or dose reduction of ATRA is required.[779] Close follow-up with an ophthalmologist is advised because these patients may suffer visual loss, which in rare cases may be irreversible.[780] Because of the high rate of ATRA-related side effects, the AML-BFM study group studied dose reduction of ATRA during induction from 45 to 25 mg/m^2/day. They found that this dose was still effective, although in pediatric patients there was still a very high rate of CNS side effects, with 57% of children exhibiting headache, increased intracranial pressure, or frank pseudotumor cerebri.[781,782] The CALGB trial C9710 included pediatric patients and used the higher dose of ATRA, but recent data demonstrated no additional benefit and only increased toxicity compared with 25 mg/m^2 dosing. Therefore this lower dose was incorporated into the recently closed first exclusively pediatric COG APL study, AAML0631, and this dose is now considered the standard of care in pediatric APL.

Arsenic Trioxide

Arsenic trioxide (As_2O_3,) has been used for decades in China as treatment for leukemia. The precise mechanism of action is actively being studied, but As_2O_3 appears to induce both differentiation and apoptosis of APL blasts and to degrade the PML-RARA fusion protein while not affecting transcriptional regulation per se.[213,218,783] As_2O_3 appears to induce nonterminal differentiation followed by apoptosis via the caspase pathway.[213,218,783-785] When As_2O_3 was used as a single agent in patients with APL, remission rates of 65% to 85% were reported and the 10-year survival was as high as 30%.[498] Later studies done in China and the United States showed favorable results, with moderate toxicity, using As_2O_3 in patients with relapsed APL who had previously received ATRA therapy.[210,784,786-788] Several studies have shown promising results using As_2O_3 in remission induction and consolidation therapy for patients with newly diagnosed APL.[789-791] One small series of 11 children with newly diagnosed APL treated with As_2O_3 as a single agent showed mild toxicity, including leukocytosis, skin changes, and mild neuropathy.[791] CR was induced in 91% of these patients, with 1 patient dying of cerebral hemorrhage during induction. With a relatively short median follow-up of 30 months, the DFS was 81% with only 1 relapse; the patient who experienced relapsed achieved a second CR, and thus the OS rate remains 91%.[791] On the U.S. phase I pediatric study of As_2O_3 for relapsed leukemia, 13 patients with relapsed APL received As_2O_3 intravenously daily at 0.15 mg/kg/dose for 5 days per week for 4 weeks with a 2-week break with maximum of 70 doses. A CR rate of 85% was observed after a median of 20 doses. Dose-limiting toxicities included rare vascular leak, anorexia, neuropathic pain, and QTc prolongation (see later).[792]

ATRA and As_2O_3 have been used safely together as induction therapy in children and adults.[213,218,783,793-795] The drugs may have a synergistic effect when used together; one study showed a shorter median time to CR in the group receiving the combination (40.5 days for ATRA alone, 31 days for As_2O_3 alone, 25.5 days for ATRA with As_2O_3).[795] The combination also provided longer duration of remission in this study. Because of these promising data, several groups have included As_2O_3 as part of induction or consolidation therapy for newly diagnosed pediatric patients with APL, with the hope of reducing the total cumulative dose of anthracycline exposure. As_2O_3 was used in a randomized fashion during consolidation in the CALGB 9710 trial that included pediatric patients through the COG and demonstrated a dramatic improvement in outcome. Patients 15 years of age and older who had the addition of As_2O_3 after a common ATRA and chemotherapy induction demonstrated significantly improved 3-year EFS (77% vs. 59%) and OS (86% vs. 77%) compared with patients who received ATRA and chemotherapy alone.[547] These results led to the nonrandom incorporation of As_2O_3 into the successor COG study

AAML0631, such that all patients nonrandomly received As_2O_3 in a dose of 0.15 mg/m^2 for 5 days a week for five courses during consolidation therapy.

As_2O_3 therapy is generally well tolerated, often with only minimal and reversible toxicity.[791,796,797] However, care must be taken with its use, because it can produce a prolonged QTc interval, which may be asymptomatic but can progress to torsades de pointes and fatal cardiac arrhythmia.[797-800] In one retrospective analysis, the rate of arrhythmia was significantly higher in African American patients (3 of 4) versus non–African-American patients (1 of 73).[801] QTc intervals should be followed closely by weekly electrocardiography during As_2O_3 treatment, and hypokalemia and hypomagnesemia should be meticulously avoided.[802] Because of the induction of cellular differentiation, As_2O_3 commonly results in a condition similar to retinoic acid syndrome, most often characterized by fluid retention and pleural and pericardial effusions.[803] This may be successfully treated in the same way as ATRA-induced retinoic acid syndrome. As_2O_3 can also cause a significant polyneuropathy, particularly when given in repeated courses.[804] Less dangerous side effects include skin changes with rash, hyperpigmentation, keratosis, and transient liver function test abnormalities. In a COG phase I study of As_2O_3 in children with refractory or relapsed acute leukemia, dose-limiting toxicities included prolonged QTc, pneumonitis, and neuropathic pain, whereas non–dose-limiting toxicities included elevated liver function test results, nausea, vomiting, abdominal pain, constipation, electrolyte changes, hyperglycemia, dermatitis, and headache.[805]

Owing to their synergistic effects, ATRA and As_2O_3 were both used upfront on the AAML0631 study and were generally well tolerated. Although used together with chemotherapy on this recently completed trial, the efficacy of this combination and recent adult studies demonstrating the ability of this combination therapy to lead to sustained remission without additional cytotoxic chemotherapy are likely to lead to future trials in which additional chemotherapy is significantly reduced or even eliminated to attain a first CR at least in standard patients. Most striking was the recent APL0406 study, which randomized adult APL patients to ATRA and As_2O_3 or ATRA and idarubicin in induction and found a 2-year EFS of 97% versus 86.7% in favor of the ATRA/As_2O_3 trial arm.[806,808] Thus the addition of anthracyclines and cytarabine may be reserved for APL patients designated high risk at diagnosis based on WBC count, those with more resistant disease (PML-RARA positive post-consolidation [see later]), or first recurrence.

Cytarabine

Although cytarabine is the backbone of induction chemotherapy for other subtypes of AML, its role in APL has been less clear.[340] The PETHEMA group completed a pediatric trial using ATRA and idarubicin as induction chemotherapy without cytarabine, and the CR rate was 92%.[771] The GIMEMA-AIEOPAIDA protocol also used ATRA and idarubicin during induction without cytarabine and showed a 96% CR rate in children.[772] However, this question was subsequently studied in a randomized clinical trial in which patients younger than 60 years and with a presenting WBC count less than 10,000/μL were randomly assigned in induction to ATRA and daunorubicin, with or without cytarabine. CR rates were comparably high for the two groups—99% with cytarabine and 94% without; however, in the cytarabine arm, the relapse rate was significantly lower (4.7% vs. 15.9%; $P = .011$), the EFS higher (93.3% vs. 77.2%; $P = .0021$), and the OS higher (97.9% vs. 89.6%; $P = .0066$). Of note, the current trials all use high cumulative anthracycline doses to achieve excellent OS rates but there is concern about long-term cardiac toxicity, particularly in pediatric patients.[807] Considering the improved results with the addition of cytarabine to the induction and consolidation regimens, several groups have been studying the use of more cytarabine with less anthracycline in pediatric patients with APL. On AAML0631, 6 g/m^{2}of cytarabine was given during the second consolidation cycle for all patients, with an additional 6 g/m^2 of cytarabine for high-risk patients. The cumulative anthracycline dose was decreased from 655 mg/m^2 on prior trials to 355 mg/m^2 for standard-risk patients and 405 mg/m^2 for high-risk patients.

Maintenance Therapy

Another difference between APL and other subtypes of AML historically has been an identified benefit from maintenance therapy. The APL93 trial randomized pediatric patients after consolidation to an arm with no further therapy or to arms with 2 years of intermittent ATRA, continuous chemotherapy with 6-mercaptopurine and methotrexate, or both ATRA and chemotherapy. Although 23% of pediatric patients in this trial experienced relapse, none of the patients who received both chemotherapy and ATRA during maintenance therapy did so.[770] In this trial, all patients with relapsed APL achieved a second CR. The 5-year EFS was 71%, and OS was 90%. The PETHEMA group also used ATRA plus 6-mercaptopurine and methotrexate during 2 years of maintenance therapy for pediatric patients and demonstrated a DFS of 82% and an OS of 87%.[771] Since these earlier studies, all recent trials for APL have included a maintenance phase of therapy. To be congruent with parallel European studies, the recently completed AAML0631 study included 2 years of maintenance therapy with ATRA, 6-mercaptopurine, and methotrexate, whereas the CALGB study only included a single year of maintenance with the same agents. However, the future of maintenance therapy in APL is uncertain. The need for chemotherapy versus ATRA alone in maintenance therapy has been raised. Preliminary results of upfront ATRA and As_2O_3 in both Italian and M.D. Anderson Cancer Center adult trials without inclusion of maintenance therapy have prompted consideration of elimination of maintenance therapy altogether.[808] Inclusion of maintenance therapy and whether any chemotherapy is necessary will be key therapeutic goals explored in upcoming trials.

Targeted Therapy

With the use of ATRA and As_2O_3, targeted therapy for APL has become a reality. Other targeted agents are also being used successfully in APL. GMTZ (see earlier) is a recombinant, humanized, anti-CD33 monoclonal antibody linked to the tumor antibiotic calicheamicin. APL cells express very high levels of CD33, making them an attractive target for GMTZ.[809] GMTZ has been used successfully as a single agent to induce remission in patients with multiply relapsed APL.[810,811] In a small series of 12 patients, GMTZ was used safely in combination with ATRA with or without idarubicin, depending on the extent of MRD, as induction therapy for patients with de novo APL with a CR rate of 84%.[812] Some groups are now studying the use of GMTZ as induction therapy in larger numbers of patients. Although not currently used initially for children with APL, GMTZ may be included for the management of high-risk patients and standard-risk patients who have a rise in their WBC count over 10,000/μL during induction therapy or, alternatively, as a strategy to induce remission after relapse in patients who have already received ATRA, As_2O_3, and cytotoxic chemotherapy.

As discussed earlier, mutations in *FLT3* have been identified in up to 43% of patients with APL, making the use of FLT3 inhibitors an attractive option. Most FLT3 inhibitors are oral agents with little toxicity. In one mouse model of APL with the *FLT3* mutation, treatment with doxorubicin alone had no impact on survival, but treatment with the FLT3 inhibitor SU11657, with or without doxorubicin, resulted in prolonged survival.[813] In another mouse model, treatment with ATRA and SU11657 resulted in the rapid regression of APL.[814] There is considerable interest in using FLT3 inhibitors in combination with ATRA and other targeted agents to improve therapy for patients with APL.

Hematopoietic Stem Cell Transplantation

Because the combination of chemotherapy and ATRA, and now ATRA and As_2O_3, results in such high cure rates for APL, HSCT is not recommended for patients in first CR, even with a matched sibling donor. There is evidence for prolonged remission without HSCT, even after relapse for patients treated with agents such as ATRA, As_2O_3, and GMTZ, especially when combined with chemotherapy.[210,784,786-788,810,811,815] Both autologous and allogeneic HSCT have been used successfully in patients with relapsed APL. For autologous HSCT to be successful, peripheral blood stem cells or bone marrow cells must be harvested once the patient has achieved negative MRD by PCR assay.[816,817] The GVL effect appears to play a role in the allogeneic HSCT treatment of APL, as evidenced by the fact that relapse rates are significantly lower after allogeneic HSCT compared with autologous HSCT and that patients who suffer a molecular relapse after allogeneic HSCT may achieve remission after the withdrawal of immunosuppression.[817-819] However, despite the lower relapse rate, because of significantly higher transplantation-related mortality (TRM) after allogeneic HSCT, OS in adults is higher after autologous HSCT than after allogeneic HSCT (postallogeneic HSCT: DFS, 92.3%; EFS, 52.2%; OS, 51.8%; TRM, 39%; and postautologous HSCT with negative preharvest PCR: DFS, 87.3%; EFS, 76.5%; OS, 75.3%; TRM, 6%).[817] In pediatric patients, allogeneic HSCT is much better tolerated. A retrospective analysis demonstrated no difference in OS after allogeneic HSCT versus autologous HSCT, although the allogeneic HSCT group had a lower relapse rate and higher TRM (postallogeneic HSCT: RR, 10%; EFS, 71%; OS, 76%; TRM, 19%; and postautologous HSCT: RR, 27%; EFS, 73%; OS, 82%; TRM, 0%).[818] Given these data, in adults, autologous HSCT is usually the preferred choice versus allogeneic HSCT for patients in second CR, whereas in children, allogeneic HSCT is often the preferred choice, particularly if a fully matched sibling donor is available.

Central Nervous System Involvement

In patients with APL, CNS disease at the time of diagnosis is rare and, because of coagulopathy, diagnostic lumbar puncture prior to the initiation of therapy is not safe for most patients. Therefore if APL is suspected, lumbar punctures should not be performed until the coagulopathy is adequately corrected and ATRA initiated. In the pre-ATRA era, CNS relapse was rarely observed in APL patients. However, while the survival rate for APL improved dramatically with the introduction of ATRA, an increasing number of CNS relapses have been reported. Unlike other subtypes of AML, most APL regimens do not include CNS prophylaxis. CNS relapse is more common in patients with a presenting WBC count higher than 10,000/μL, with microgranular variant morphology, and with bcr3 PML-RARA isoform, all of which are also associated with the presence of an *FLT3* ITD and all of which are more common in pediatric patients.[165,744-749,753,770,809,820,821] Although there was initially concern that ATRA itself was contributing to CNS relapses, it now seems that ATRA does not penetrate the CNS well and, with more patients surviving APL therapy, this likely contributes to the higher rate of CNS relapse currently observed.[820-823] Several groups have now initiated a screening lumbar puncture at the time of CR and use prophylactic intrathecal chemotherapy, usually with cytarabine and methotrexate, for patients at high risk for CNS relapse.[821,824] On AAML0631, prophylactic cytarabine was given intrathecally in consolidation 2, 3, 4 (for high-risk patients) and the first maintenance course but at a lower dose of 30 mg (25 mg for children >2 years of age but <3 years of age) compared with the 70-mg given as standard dosing in other subtypes of AML. Given the infrequency of CNS positivity in APL, future studies may eliminate intrathecal therapy entirely.

Minimal Residual Disease Monitoring

Detection of the *PML-RARA* fusion gene by reverse-transcriptase PCR (RT-PCR) has become a valuable tool for measuring MRD in APL. RT-PCR positivity at the end of induction does not seem to portend a higher risk for relapse and therefore should not be checked at that time point, but RT-PCR positivity after consolidation does carry a significantly higher risk for relapse. RT-PCR positivity during maintenance or after therapy is indicative of impending relapse in almost all patients.[772,825,826] MRD analysis is being used to identify high-risk groups that require more intensive therapy for cure.[772] When detected early by RT-PCR, molecular relapse may also be easier to treat than frank morphologic relapse because of the lower disease burden and the treatment of a healthier asymptomatic patient.[827] In many studies, RT-PCR analysis is carried out on bone marrow cells and evidence regarding analysis of peripheral blood is not as clear,[828] thus *PML-RARA* surveillance on AAML0631 mandated bone marrow samples. However, the frequency of relapse after therapy including As_2O_3 is so rare for standard-risk patients[829,830] that whether follow-up on future trials will require the invasiveness of bone marrow evaluations remains to be determined. There is also controversy regarding the threshold for a "positive" result; some groups do not consider a result a true positive unless there are two positive results separated by 2 to 4 weeks. However, in the event that suspicion is significant for recurrence based on a rising level of PML-RARA transcript in the peripheral blood, a bone marrow evaluation should be conducted to look for molecular, cytogenetic, and hematologic signs of relapse.

Relapsed Disease

In the current ATRA and As_2O_3 era, relapsed APL is a rare occurrence and there is limited experience on what therapeutic strategy to undertake in children who have already received ATRA, As_2O_3, and chemotherapy. Given their efficacy, reinduction with combination ATRA and As_2O_3 is a reasonable strategy if previously well tolerated, although it is unclear whether the addition of chemotherapy provides any further benefit or merely contributes to toxicity. Currently, patients with relapsed APL may have already seen a significant cumulative dose of anthracycline, such that additional anthracycline may push the normally accepted lifetime ceilings with which most clinicians are comfortable. However, the concomitant use of cardioprotectants, such as dexrazoxane, may provide the opportunity to provide further anthracycline therapy at relapse. Furthermore, if future studies show the initial use of chemotherapy and anthracyclines in particular may be significantly reduced owing to the efficacy of combination ATRA and As_2O_3, it may enable chemotherapy to be reserved for relapses and refractory cases. Regardless, particularly with early relapse, given the opportunity for GVL effect and the improvement in both high-resolution HLA typing and better supportive care, after reinduction, best available donor allogeneic transplant would be recommended by most experts.[831] However, on prior studies, TRM with allogeneic HSCT was higher than with autologous transplant, although there was no significant difference in 5-year OS or EFS,[818,832] so this decision should not be made lightly. With later relapses, the ability to induce a second sustained CR with ATRA, As_2O_3, and chemotherapy without HSCT may be a feasible alternative, although with small numbers of patients most of these data are anecdotal.[754]

DOWN SYNDROME WITH TRANSIENT DISORDER AND ACUTE MYELOGENOUS LEUKEMIA

Down Syndrome with Transient Myeloproliferative Disorder

Pathobiology

Down syndrome, characterized by trisomy 21, is the most common congenital chromosomal abnormality, occurring in an estimated 1 in 600 to 1000 live births.[833,834] Up to 10% of infants with Down syndrome are born with a transient myeloproliferative disorder (TMD) (also referred to as transient leukemia [TL] or transient abnormal myelopoiesis [TAM]). TMD is characterized by the presence of immature megakaryoblasts in the liver, bone marrow, and peripheral blood. The disorder usually spontaneously regresses within 3 months.[71,835-837] By morphology, TMD blasts are identical to AMKL blasts and, even though in most cases they regress, up to 30% of Down syndrome infants with TMD subsequently develop AMKL within 3 years.[838,839] Studies have shown that TMD blasts are clonal and that the same clone subsequently evolves into AMKL in a subset of patients.[840-843]

In 2002, Wechsler and colleagues[267] first reported mutations in exon 2 of *GATA1* in Down syndrome–associated AMKL. Soon thereafter, several groups reported that *GATA1* mutations were detectable in almost all patients with Down syndrome–associated TMD.[844-849] Interestingly, *GATA1* mutations have also been detected in approximately 10% of Down syndrome patients who have never been diagnosed with a hematologic abnormality.[850] It is not clear whether these patients have a history of subclinical TMD that regressed without detection or if the mutation simply did not result in the TMD phenotype in these cases. Normal GATA1 plays a vital role in the maturation of erythroid cells and megakaryocytes.[851] The *GATA1* mutations in Down syndrome TMD and AMKL result in GATA1s, a truncated protein lacking the amino-terminal activation domain.[847,852,853] GATA1s appears to be a normal isoform of GATA1 and has been detected in human hematopoietic cell lines and mouse fetal liver. However, because *GATA1* is an X-linked gene, only the truncated GATA1s is expressed in Down syndrome TMD and AMKL blasts. It has been hypothesized that the presence of a trisomy 21 in conjunction with a GATA1s allows abnormal proliferation of megakaryoblasts, but only in the fetal hematopoietic system (i.e., the fetal liver); thus TMD resolves with the loss of fetal hematopoiesis.[835,854] Although the combination of trisomy 21 and a *GATA1* mutation appears sufficient to result in TMD, this is not sufficient to result in frank leukemia, and only if additional mutations are accumulated over time will the disease progress to frank AMKL.

Wilms tumor gene *(WT1)* levels detected by PCR assay are elevated in patients with TMD. Levels normalized in four of five patients studied who had regression of TMD, with no further sequelae, but did not normalize in the fifth, who went on to develop AMKL at 11 months of age, making this an attractive marker for MRD and prognosis.[855] Both gain- and loss-of-function mutations in Janus kinase 3 *(JAK3)* have been identified in a subset of patients with TMD, although the prognostic relevance of this is not yet known.[856,857]

Clinical Presentation

Because Down syndrome infants with TMD are often asymptomatic, the incidence of 10% may be an underestimate, because many patients may have TMD that spontaneously regresses, without ever being detected.[846,858-861]

For this reason, many physicians obtain a routine screening complete blood cell (CBC) count at birth for all infants with known or suspected Down syndrome. However, some infants with Down syndrome have a dramatic presentation of TMD at or shortly after birth, with hydrops fetalis, pleural and pericardial effusions, ascites, and massive hepatosplenomegaly. These patients may rapidly progress to liver fibrosis or multisystem organ failure, both of which are most often fatal.[837,862-865] In the Pediatric Oncology Group (POG) trial 9481, 48 children with TMD were followed prospectively; 19% developed life-threatening disease with hepatic fibrosis or cardiopulmonary failure, with an overall mortality at 3 months of age of 10.4%.[837] Another retrospective analysis from Japan has shown that 22.9% of patients with TMD die before the age of 6 months, and the main causes of death were hepatic or cardiopulmonary failure.[866] In this study, early gestational age, WBC count greater than 100,000/μL, high percentage of peripheral blasts, elevated aspartate aminotransferase (AST), elevated direct bilirubin, and low Apgar score were significantly associated with poor survival. They noted that only 7.7% of term Down syndrome infants with a WBC count less than 100,000/μL died, whereas 54.5% of preterm infants with a WBC count higher than 100,000/μL died, suggesting that risk stratification may be possible to determine high-risk subgroups of patients who require earlier and more aggressive therapy.

Treatment

Because most patients with TMD will exhibit spontaneous regression, treatment often consists of supportive care only. Many groups, including COG protocols 2971 and 08B1, have recommended supportive care only for TMD patients unless they exhibit signs or symptoms of life-threatening disease, including hyperviscosity, with a total blast count higher than 100,000/μL, organomegaly causing respiratory compromise, congestive heart failure not caused by a congenital heart defect, hydrops fetalis, life-threatening hepatic dysfunction, defined as significant (grade 4 level toxicity) DIC, hyperbilirubinemia, ascites, or transaminitis.[837,867] For patients who require therapy, the choices include leukapheresis, exchange transfusion, or low-dose cytarabine.[862] Low-dose cytarabine has been effective when used early in critically ill patients.[868] In patients with hyperleukocytosis or who require therapy with cytarabine, treatment to prevent the consequences of rapid tumor lysis (see earlier) should be promptly initiated.

Down Syndrome with Acute Myelogenous Leukemia

Pathobiology

Children with Down syndrome have a markedly increased risk for leukemia during the first 10 years of life. Acute leukemia is 10 to 20 times more common in children with Down syndrome than in children in the general population, and leukemia in Down syndrome patients younger than 4 years is most commonly AML (specifically AMKL), whereas leukemia in older children with Down syndrome is most commonly ALL.[838,869-878] The ratio of ALL to AML is approximately 1 : 1 in children with Down syndrome, but in the first 4 years of life, AML is 100 times more common than ALL.[72] Although AMKL is a rare subtype of AML in the general population, it is the predominant form of AML in children with Down syndrome, making Down syndrome patients 500 times more likely than other children to develop AMKL. Unlike other children with AML, AMKL in children with Down syndrome often manifests after a period of myelodysplasia, usually characterized by months of thrombocytopenia and later by anemia.[72,879,880] Most cases of AMKL in Down syndrome patients are preceded by TMD (see earlier).[850,881] Several studies have confirmed that when there is a proven antecedent TMD, the same TMD clone subsequently evolves into AMKL.[844,846,882,883]

Also characteristic of AMKL in Down syndrome are *GATA1* mutations (see earlier). Because *GATA1* encodes a transcription factor essential for megakaryocyte development, samples from patients with AMKL were studied for evidence of *GATA1* mutations.[267] Mutations in exon 2 of GATA1 were detected in AMKL blasts from Down syndrome patients but not in other subtypes of AML in Down syndrome patients or in AMKL blasts from non–Down syndrome patients. Several subsequent studies have confirmed *GATA1* mutations leading to a premature stop codon in almost all cases of Down syndrome–associated AMKL.[844-849] *GATA1* mutations have been identified in the blood spots of three of four Down syndrome patients with AMKL who had not been previously diagnosed with TMD, suggesting that in most cases of AMKL the mutation has been present since birth.[846,850,882,883] Down syndrome patients who develop AML after the age of 4 years do not usually have *GATA1*-mutated AMKL but have AML more typical of the general pediatric population (non–Down syndrome AML). This disease is not as sensitive to chemotherapy and does not carry the exceptionally good prognosis carried by Down syndrome AMKL (see later).[884-886]

Additional mutations beyond the *GATA1* mutation in the presence of trisomy 21 are necessary to produce AMKL. The good-risk translocations common in other forms of pediatric AML, including t(8;21), t(15;17), inv(16), and t(9;11), are almost never seen in Down syndrome AMKL, although they are more commonly reported in Down syndrome patients who develop AML after the age of 4.[873,875,886-888] Other than trisomy 21, trisomy 8 is the most common cytogenetic abnormality in Down syndrome AMKL. Other translocations commonly reported in AMKL in the absence of Down syndrome, including t(1;22) and t(1;3), are only rarely documented in Down syndrome AMKL.[889] Monosomy 7, a widely accepted marker of pediatric and adult high-risk AML in the absence of Down syndrome, is also seen in 3.5% to 10% of patients with Down syndrome and AML and, although data are limited, it is generally associated with a worse outcome (see later).[890-892] Approximately 25% of patients have no cytogenetic abnormalities other than the constitutional trisomy 21, although some patients will exhibit tetrasomy 21. As in TMD, overexpression of *WT1* and mutations in *JAK3* have been reported in Down syndrome AMKL.[855-857] More recently, next generation sequencing approaches have identified a number of potential somatic mutational drivers that might contribute to the progression of TMD to AMKL including mutations in the cohesin complex; the epigenetic regulator, EZH2; as well as activating lesions in the RAS, WNT, mitogen activated protein kinase (MAPK) and phosphoinositide 3-kinase (PI3K) pathways.[892a,892b]

Clinical Presentation

Children with Down syndrome who develop AML present at a younger age than average for childhood AML, with 60% to 70% of patients diagnosed when they are younger than 2 years.[70,873,875,884,887,888] Down syndrome patients generally present with lower total WBC counts (median, 7,000 to 10,000/µL) and lower platelet counts (median, 25,000 to 30,000/µL) than other children. Hepatosplenomegaly is more common in Down syndrome patients with AML than in other children, whereas lymphadenopathy and CNS involvement are less common. Down syndrome AMKL is frequently preceded by TMD, which is almost absent in non–Down syndrome patients, or MDS, which is far less common in non–Down syndrome patients. Older Down syndrome patients with AML have presenting signs and symptoms that more closely mirror those of the general population, reflecting the virtual lack of AMKL with *GATA1* mutations in patients older than 5 years.

Treatment and Outcome

Many children with Down syndrome have been entered into large clinical trials since 1982, when legislation was passed that prohibits withholding medical intervention from children with disabilities.[72] In the early clinical trials that included patients with Down syndrome and AML, the outcome was poor because of excessive toxicity. The associated congenital abnormalities, increased susceptibility to infection, and altered drug metabolism in patients with Down syndrome made it challenging to find appropriate therapy for this group. However, while general medical care for children with Down syndrome has improved, the outcome for children with AML and Down syndrome has also improved. Multiple studies from around the world have consistently demonstrated that Down syndrome AML patients have a better overall prognosis than children with AML in the general population.[530,873,875,884,887,888,893] A remarkable feature of AML in children with Down syndrome is its extraordinary responsiveness to AML chemotherapy.[72,874] Compared with non–Down syndrome AML, leukemic blasts are 4.5-fold and 12-fold more sensitive in vitro to cytarabine (median half maximal inhibitory concentration [IC_{50}], 77.5 vs. 350.9 nM) and daunorubicin (median $IC_{50,}$ 5.8 vs. 71.2 nM), respectively.[894,895] The increased sensitivity of Down syndrome AML blasts to cytarabine has been explained by a 5.2-fold greater accumulation of the active drug metabolite cytarabine-CTP compared with non–Down syndrome AML blasts.[896] Down syndrome AMKL blasts are significantly more sensitive to other chemotherapy agents, including amsacrine (16-fold), etoposide (20-fold), 6-thioguanine (3-fold), busulfan (5-fold), and vincristine (23-fold).[897] In addition to constitutionally expressed genes encoded on chromosome 21, which modulate drug metabolism in Down syndrome AML blasts, such as cystathionine-β-synthase (CBS),[898-900] the expression of mutant GATA1 protein itself contributes to increased drug accumulation.[901,902] In addition, the cytidine deaminase (CDA) levels in Down syndrome AMKL blasts are low, leading also to increased sensitivity to cytarabine. The CDA promoter contains several binding sites for GATA1, suggesting that *GATA1* mutations may contribute to the sensitivity of these blasts.[900]

Observations of increased in vitro sensitivity of Down syndrome AMKL blasts to cytotoxic drugs have been complemented by pioneering studies in which very low doses of cytarabine, which were administered over a prolonged period of time (10 mg/m^2 subcutaneously for 12 hours for 7 days every 2 weeks for 2 years),[903,904] resulted in durable remissions in as many as 67% of cases (intention to treat analysis[903]). Although outcomes of the very-low-dose cytarabine regimen eventually did not match those of standard dose cytarabine,[904] the observation highlights a unique degree of drug sensitivity of Down syndrome AMKL blasts to cytarabine that is not encountered in pediatric non–Down syndrome AML. Recently, Japanese investigators showed that high-dose cytarabine could successfully be eliminated from a treatment protocol for Down syndrome AML while maintaining a 4-year EFS of 83%.[892] In parallel, studies maximizing dose intensity for the treatment of AML, although successful in the general pediatric population,[411,905] did not translate into any improvements in EFS for patients with Down syndrome and AML owing to excessive mortality during induction therapy in this group.[905] In the German collaborative AML-BFM93 protocol, children with Down syndrome fared worse than other patients because of an increased frequency of infectious complications, but none of the patients experienced relapse and EFS was approximately 70%.[886,906] Therefore, in the subsequent AML-BFM98 protocol, Down syndrome patients received a reduced intensity regimen and the EFS improved dramatically, to almost 90%. In the Nordic Society for Paediatric Haematology and Oncology-Acute Myeloid Leukaemia (NOPHO-AML) trials, the earlier, more intensive NOPHO-AML88 trial showed a high death rate from infectious complications for Down syndrome patients with AML, with an EFS of only 47%, compared with much better outcomes in the later, less-intensive NOPHO-AML93 trial, with an EFS of 85% (76% for those who received full-dose therapy and 92% for those who received reduced-dose therapy).[907] The MRC trials showed similar results with Down syndrome patients receiving the same standard therapy as other patients, resulting in a higher rate of death from toxicity but lower relapse rate when compared with other children.[908] Perhaps the most striking example comes from the CCG 2891 study. In this study, all children were randomly assigned to receive induction chemotherapy with intensive timing (i.e., proceeding with the second cycle, regardless of counts) versus standard timing (i.e., awaiting count recovery before initiating the second cycle). The Down syndrome patients in the intensive timing arm of the study suffered a 32% mortality rate compared with an 11% mortality rate for the remainder of the patients, prompting early closure of that study arm for Down syndrome patients.[875] Standard timing induction for Down syndrome patients resulted in an impressively high CR rate of 95% (2.4% with toxic death and 2.4% with resistant disease).[875] Postremission consolidation with allogeneic HSCT in this trial also resulted in an unacceptably high treatment-related mortality for Down syndrome patients, with only 33% survival at 4 years.[875] In this study, standard timing induction followed by consolidation with chemotherapy was clearly the superior treatment for Down syndrome patients, with a 4-year DFS of 88% compared with a DFS of only 42% for this regimen in the non–Down syndrome patients.[875] Given these collective data, COG trial A2971 used a less intensive approach for Down syndrome patients, with four cycles of standard timing low-dose cytarabine, daunorubicin, and thioguanine, followed by a cycle of high-dose cytarabine with asparaginase and then intrathecal therapy.[909] Five-year outcome data were comparable to those of CCG2891 with OS of 84% and EFS of 79%.[910]

The first toxicity to which DS-AML patients were identified as being particularly susceptible was cardiotoxicity. On the POG9421 AML study in which the total cumulative anthracycline equivalent dose was 535 mg/m^2, 21% of DS children developed congestive heart failure with diminished shortening fractions on echocardiogram requiring chronic diuretics and/or inotropes. Sixty percent of these patients had congenital heart defects, and a third of the patients with cardiac dysfunction died.[911] On both CCG2891 and A2971, the cumulative anthracycline dose was reduced to 350 mg/m^2, but together with the overall reduction in chemotherapy on A2971, grade 3 or higher cardiac toxicity occurred in only 4% of patients during induction and 2% of patients during intensification.[910] The most recent COG Down syndrome AML study, AAML0431, was designed to further reduce the cumulative dose of anthracycline based on A2971 and gave a cumulative dose of only 240 mg/m^2. The study closed in December 2011 and to date no significant cardiac toxicity has been reported (J. Taub, personal communication, June 2014). However, the second cycle of induction chemotherapy during which high-dose cytarabine is given resulted in the greatest number of adverse events, including longest median duration, longest period of myelosuppression, and highest rate of bacterial infections. These toxicities, together with prior data demonstrating the exquisite sensitivity of Down syndrome AMKL blasts to cytarabine, have prompted plans for elimination of high-dose cytarabine for the majority of patients on the upcoming COG Down syndrome AML trial.

Despite the overall favorable outcomes for AML in Down syndrome, 15% to 25% of patients do not achieve long-term survival with current treatment protocols, predominantly owing to relapse or refractory disease.[891,892,912] Lack of response to therapy is associated with very poor outcomes with survival rates of 20-26% even after HSCT.[912a,912b] Prognostic markers in AML in Down syndrome are few because many of the predictive genetic lesions discussed earlier for non–Down syndrome AML are very infrequent findings in Down syndrome patients. To date, age older than 4 years and monosomy 7 appear the only known high-risk factors, both of which are relatively rare, and the outcome in patients harboring a monosomy 7 is still somewhat controversial. In the BFM-93 trial, 3 of 4 patients older than 4 years lacked the typical AMKL of Down syndrome and only 1 of the 3 survived.[886] In a combined analysis of European trials, 17 of 317 Down syndrome patients diagnosed with AML were older than 4 years.[885] DNA was available from blasts of 10 of these patients and, of these, 3 children younger than 7 years had the characteristic AMKL and 1 additional younger child had M0 AML with a *GATA1* mutation. Of the 6 remaining patients without AMKL or a *GATA1* mutation, all were 7 years of age or older and 4 experienced relapse. In CCG 2891, children older than 4 years of age ($n = 9$) had a significantly lower EFS at 6 years of only 33% ± 31%.[891] On A2971, patients younger than 4 years of age fared significantly better than older children (5 year EFS, 81% ± 7% vs. 33% ± 38%), although only 6 children older than age 4 years were included.[913] An international retrospective study of 451 Down syndrome patients with AML found monosomy 7 was associated with a moderately worse outcome, with a 5-year EFS of 69%. CCG studies 2891 and A2971, as well as a recent Japanese study,[892] found that only 11 of 16 patients with Down syndrome and AML and monosomy 7 were in complete clinical remission. These limited data suggest that older children with Down syndrome and AML, particularly given the absence of *GATA1* mutations, have disease more reminiscent of non–Down syndrome AML and should be treated more aggressively. Similarly, the presence of monosomy 7 may contribute to an inferior outcome and justify more intensive therapy for this cohort. However, most children with Down syndrome and AML are younger than age 4 years and lack monosomy 7. For this group, similar to non–Down syndrome AML, MRD after induction may enable the ability to identify high-risk patients. These data will be forthcoming from the recently closed AAML0431 study and will inform future clinical trials.

MYELODYSPLASTIC SYNDROMES

The myelodysplastic syndromes are a heterogeneous group of clonal hematologic disorders characterized by ineffective hematopoiesis, progressive cytopenias, dysplastic transformation of hematopoietic cells, and a propensity for transformation into AML.[914] MDS is most common in patients older than 60 years, but at the same time it is an unusual but clinically important disease of childhood.

Diagnosis and Classification

Morphology

The morphologic features of MDS include bone marrow dysplastic changes involving all three cell lineages (i.e., trilineage dysplasia). A common theme underlying these features is asynchrony between the usual cytoplasmic and nuclear differentiation programs, so that nuclei appear abnormal and less mature than the features of the surrounding cytoplasm. Figure 51-8 The hallmark of myelodysplastic syndrome (MDS) is the loss of specific chromosomal regions. Deletions of the long arm of chromosomes 5 and 7 (5q–, 7q–) occur in de novo MDS and acute myelogenous leukemia (AML) but much more frequently in therapy-related MDS and therapy-related AML after treatment with alkylating agents. 20q– abnormalities are less common but also occur in both de novo MDS and AML and after prior chemotherapy. *(Data from Heaney ML, Golde DW: Myelodysplasia.* N Engl J Med *340:1649–1660, 1999; Hofmann WK, Lubbert M, Hoelzer D, et al: Myelodysplastic syndromes.* Hematol J *5:1–8, 2004; Pedersen-Bjergaard J, Andersen MT, Andersen MK: Genetic pathways in the pathogenesis of therapy-related myelodysplasia and acute myeloid leukemia.* Hematol Am Soc Hematol Educ Prog *2007:392–397, 2007.)*

include megaloblastoid changes, perinuclear ringlike deposits of iron (i.e., ringed sideroblasts), multinucleation, nuclear budding and fragmentation, and an increased percentage of immature forms. Dysmegakaryopoiesis is characterized by micromegakaryocytes, abnormal nuclei, and abnormal nuclear lobulation. The dysplastic features of the granulocytic cells comprise immature forms, hypogranulation, and the Pelger-Huët–type abnormality. Monocytic dysplasia includes increased numbers of bone marrow monocytes, abnormal granulation with increased azurophilic granules, hemophagocytosis, abnormal nuclei, and giant forms. Bone marrow cellularity is usually normal or increased, and the reticulin concentration is increased in most cases.

Patients with MDS may present initially with a single peripheral blood cytopenia, which usually progresses to pancytopenia with anemia, leukopenia, and thrombocytopenia. The anemia in MDS is caused by ineffective erythropoiesis with low reticulocyte counts and macrocytosis, teardrop cell formation, and moderate poikilocytosis. In addition, megaloblastoid circulating nucleated red blood cells are frequently detected. Peripheral blood dysgranulopoiesis manifests as circulating myeloblasts, progranulocytes, and Pelger-Huët cells. Thus early signs may be a falling hematocrit with increasing mean corpuscular volume or unexplained thrombocytopenia. The peripheral blood may also exhibit increased numbers of monocytes and monoblasts.

Cytogenetics

Cytogenetic abnormalities are common in children with MDS and were reported in 59% of 227 children tested in one study.[915] Chromosomal deletions are the hallmark of MDS and frequently involve the long arms of chromosomes 5, 7, and 20 (Fig. 51-8). Other common cytogenetic abnormalities include trisomy 8, del(17p), +21, inv(1), and t(7;16).[253,916,917] These chromosomal abnormalities are accompanied by other complex karyotypic changes in many cases. Other abnormalities that have been reported in pediatric cases of MDS include +6, +9, and +11, whereas deletions of chromosomes 11, 12, and 13 and Y are rare.[918] Common balanced chromosomal translocations found in AML, such as t(8;21), t(15;17), and inv(16), are not usually detected in MDS.[919]

Classification

In 1982, the FAB cooperative group defined five categories for the adult myelodysplastic and myeloproliferative syndromes—refractory anemia (RA), RA with ringed sideroblasts (RARS), RA with excess blasts (RAEB), RA with excess blasts in transformation (RAEB-T), and chronic myelomonocytic leukemia (CMML).[324,325,920,921] Classification of childhood MDS into defined FAB subcategories is not always straightforward. Many children show overlapping features of MPD and MDS, particularly patients with JMML and infant monosomy 7 syndrome.[254] The classification of pediatric MDS is also complicated by the fact that some children develop MDS in the context of inherited predispositions such as neurofibromatosis type 1, severe congenital neutropenia, and Down syndrome.[254] Using the FAB system of classification, the most common subtypes of MDS in children are RAEB and RAEB-T, whereas RA and RARS are uncommon and CMML is rare.

The WHO proposed a revised classification of MDS in 1997. The WHO system includes the following changes to the FAB criteria: elimination of the RAEB-T subtype through a reduction in the marrow blast count to 20% for the diagnosis of AML and the division of the RAEB subtype into RAEB-I, consisting of 5% to 10% marrow blasts, and RAEB-II, comprising 11% to 20% blasts.[309,328,922] Other WHO recommendations include two new categories for patients with refractory cytopenias with multilineage dysplasia and a new category for unclassified MDS. In the new system, CMML is removed completely and reclassified as a myeloproliferative disorder.

A third classification system is used in parallel with the FAB and WHO systems, the IPSS Scoring System.[923] This system assigns a numeric value to each of the number of cytopenias, cytogenetic abnormalities, and percentage of bone marrow blasts, and a higher score is associated with a poor prognosis. The use of the IPSS in children is of somewhat limited value. The only factors found to be predictive were bone marrow blasts greater than 5% and platelet counts greater than 100,000/μL.[924,925]

Pathophysiology

Evidence for clonality in MDS comes primarily from nonrandom X-inactivation studies (see earlier) performed on the bone marrow cells of female patients with MDS. These studies have demonstrated clonal involvement of hematopoietic cells in this disorder.[926-928] The trilineage dysplasia that characterizes MDS strongly suggests that the cell of origin resides within the compartment containing early hematopoietic progenitors or stem cells with multilineage potential.[929] Early mutations in stem cells may cause a failure in myeloid cell maturation, as well as enhanced apoptosis, leading to dysplasia, whereas subsequent defects affecting myeloid cell proliferation and the development of antiapoptotic signals may cause the clonal expansion of aberrant cells and frank leukemia. An increased level of apoptosis has been documented in early MDS, which is followed by decreased blast cell apoptosis in patients whose disease transforms to AML. MDS cells have been found to overexpress certain cell surface death receptors and their ligands, which may be induced as a result of signals from inflammatory cells present in the hematopoietic microenvironment.[919] Patients with more advanced MDS (FAB RAEB) have decreased levels of death receptor expression compared with early-stage MDS and increased expression levels of antiapoptotic factors, such as BCL2.[930,931]

The most common chromosomal abnormalities in childhood MDS involve large deletions, but little is known about the genes contained in the deleted segment[916,932-934] and whether these large genetic aberrations are inciting events leading to the development of MDS or represent secondary events. Ebert and colleagues[935] used an RNA interference screen to identify a putative gene deleted from the distal end of the long arm of chromosome 5 in 5q– syndrome, a subtype of MDS commonly encountered in older women but uncommon in pediatric patients. They found that haploinsufficiency of *RPS14*, a gene that codes for a component of the 40S ribosomal subunit, results in the characteristic phenotype of selectively diminished erythropoiesis, with preservation of megakaryocyte maturation. Moreover, the introduction of a lentiviral vector expressing *RPS14* into the CD34+ cells of MDS patients demonstrates restored erythroid differentiation exclusively in those with a 5q– genotype. These elegant studies convincingly identified a specific genetic lesion underlying the 5q– syndrome and also established this ribosomal protein as critical in erythroid development.[935] This finding is in keeping with the elucidated role of other ribosomal proteins in a number of bone marrow failure syndromes, such as Diamond-Blackfan anemia.[936]

5q– syndrome has a reasonably favorable outcome because of its natural history of slower progression to AML and sensitivity to treatment with lenalidomide, an analogue of thalidomide.[937,938] In this select population, lenalidomide (Revlimid) reduces the need for red cell transfusions and induces significant cytogenetic responses, which has resulted in its recent approval by the FDA for the treatment of MDS patients with 5q– syndrome.[939] Although this therapy has demonstrated impressive efficacy in this condition, deletion of this distal region of 5q is relatively rare. Only a minority of MDS patients without this cytogenetic abnormality respond to lenalidomide, and responders possess no distinguishing clinical or laboratory characteristics compared with nonresponders.[940] However, other studies[941] suggest that responders have a unique genetic signature consisting of low expression levels of genes typically involved in terminal erythroid differentiation. These results imply that the restoration of normal red cell development underlies lenalidomide's mechanism of action, particularly in non-5q–, whereas in 5q– syndrome, lenalidomide may more directly suppress the malignant clone.[942] Clinically, this suggests that genetic profiling could be used to select a group of MDS patients without 5q– deletions who would be more likely to respond to this agent.

These large deletions also likely contain certain important tumor suppressor genes, the elimination of which contributes to MDS pathogenesis. For example, we completed a detailed analysis of the more proximally deleted region of the long arm of chromosome 5 and identified α-catenin as a novel tumor suppressor gene in MDS.[252] In both primary patient samples and AML cell lines with a deletion of 5q–, α-catenin expression levels were found to be specifically and substantially decreased through the combination of a deletion on one chromosome and epigenetic silencing by hypermethylation and histone deacetylation of the promoter of the second allele. Another group has identified the WT1 transcription factor, early growth response 1 *(EGR1)*, as a putative candidate gene in this same region and demonstrated that haploinsufficiency of this tumor suppressor gene can result in MDS or MPD after treatment with an alkylating agent.[943]

In addition to gene deletions, a number of other genes have been found to contribute to MDS pathogenesis. Balanced translocations, such as those seen in de novo AML, are uncommon in MDS, but some of the same genes may be involved. Other genetic lesions appear to be specific for MDS. We and others have shown that certain *HOX* genes, most notably *HOXA9*, are overexpressed in the HSCs of patients with MDS.[944-946] Translocations involving *HOX* genes and the nucleoporin gene *(NUP98)* on chromosome 11, including *NUP98-HOXA9*[947] and *NUP98-HOXA13,*[948] have been found in rare patients with MDS. Certain genetic abnormalities are more characteristic after prior treatment with chemotherapy. Overexpression of the *EVI1* transcription factor on chromosome 3, either through gene rearrangements or rare translocations, has been associated with MDS after chemotherapy.[949-951] Similarly, nucleophosmin and myeloid leukemia factor 1 *(NPM-MLF1)* fusion gene, formed as a result of a t(3;5) chromosomal translocation, occurs in rare cases of MDS or AML arising from MDS.[952,953] Mutations in *RAS* and *FLT3*, such as those seen in de novo AML, are found in patients with MDS, particularly those with 7q– and often after treatment with alkylating agents.[954] These patients may also have mutations in the *AML1* gene, whereas the *AML1-ETO* translocation is rare in MDS.[955,956] Prior treatment with alkylators can also lead to MDS with 5q–, and these patients often have a mutation in *TP53*, a gene that is also frequently mutated in AML cases with a complex aberrant karyotype, which include a 5q deletion, but rarely in classic de novo AML.[955-957]

More recently, owing to responses in MDS to epigenetic regulating agents, such as DNA methyltransferase inhibitors, and the identification of a number of mutations in epigenetic regulating genes in AML, a series of studies using high-throughput genomic approaches have identified similar abnormalities in MDS. Mutations in *TET2* occur in approximately 25% of adults with MDS,[958] whereas *DNMT3A* and *IDH1* and *IDH2* mutations were found in 3% to 10% of patients.[959-962] In addition, mutations have been found in histone modifying enzymes, including *EZH2*, which is rare in de novo AML,[963,964] and *ASXL1*, both associated with a worse outcome in adult MDS.[965,966] Finally, novel mutations in genes involved in the assembly of the spliceosome that removes introns from transcribed pre-mRNA have been identified. The genes most commonly involved include *SF3B1* and *U2AF1*.[967-969] However, MDS is much rarer in children, and all of these mutations appear to be rare in pediatric MDS; thus their impact on pathogenesis and prognosis remain uncertain at this time.[970]

Inherited and Environmental Predisposing Factors

Several environmental exposures and inherited conditions are associated with an increased risk for MDS and AML. As noted, alkylating agents and topoisomerase II inhibitors can predispose to MDS and AML, which can occur as treatment-related second malignancies in patients treated for ALL and many other types of cancer. Secondary disease associated with alkylating agent chemotherapy tends to occur from 3 to 11 years after treatment, after which the incidence appears to plateau.[971-973] The disease often presents as MDS, and an underlying predisposition may involve defective DNA repair mechanisms. Commonly, there are deletions of chromosomes 5 or 7.[972] *MLL* gene rearrangements are often found in AML cases that arise after treatment with topoisomerase II inhibitors such as etoposide, but these patients tend to present with frank AML after a short latency of 1 to 3 years from therapy and without an MDS prodrome.[972,974]

A number of genetic conditions are associated with an increased risk for MDS and subsequent AML, particularly the bone marrow failure syndromes and chromosomal breakage disorders. Some disorders, such as Fanconi anemia, in which patients demonstrate both pancytopenia and increased sensitivity to DNA damage, suggest that impaired DNA repair may be a mechanism for malignant transformation. However, other marrow failure syndromes are not characterized by increased susceptibility to chromosomal breakage such as dyskeratosis congenita or may present predominantly as a single cytopenia, such as neutropenia in Shwachman-Diamond syndrome, anemia in Diamond-Blackfan anemia, and low platelets in amegakaryocytic thrombocytopenia. The evolution of MDS in these conditions is variable (10% to 20% in Shwachman-Diamond syndrome compared with 1% in Diamond-Blackfan anemia), and the mechanism remains elusive, although defective ribosomal processing may be involved, given the identified functions of the target proteins involved in a number of these conditions.[919,975] In addition, there are several MDS/AML predisposition genes that have been identified, including loss-of-function alterations affecting the key hematopoietic transcription factor genes, *RUNX1*, *CEBPA*, and, most recently, *GATA2*. Germline mutations in *RUNX1* can result in familial platelet disorder with a propensity to myeloid malignancy (FPD/AML). These patients have thrombocytopenia or normal platelet numbers but abnormal platelet function and can evolve into MDS or AML.[76-79] A recently identified related disorder termed thrombocytopenia type 2 has been linked to mutations in a gene called *ANKRD26* at 10p11.2-p12 in a number of Italian and American families with a progression to frank myeloid and lymphoid malignancies, with an MDS prodrome rarely described.[976] Deletions of the granulocyte-specifying gene *CEPBA* have been described in a small number of families resulting in an FAB M1 or M2 subtype AML; however, an MDS prodrome has not been described. The *CEBPA* mutations are autosomal dominant, similar to those involving *RUNX1*, but fully penetrant, in contrast to the highly variable penetrance observed for *RUNX1* lesions.[78,977-979] Loss-of-function mutations or deletions involving *GATA2*, which plays a role in early blood, vascular, and lymphatic development, have been described as a cause of a familial MDS/AML syndrome. These patients may present with neutropenia, often with an associated monocytopenia[80] or with so-called monoMAC syndrome/DCML deficiency associated with monocytopenia and dendritic, B-cell, and NK-cell lymphopenias with a predisposition to nontuberculosis mycobacterial infections. Some of these patients may also develop lymphedema.[80,980,981]

Clinical Presentation

Children with MDS generally present with the signs and symptoms associated with bone marrow failure. Abnormalities in the peripheral blood may also be detected on routine medical examinations in asymptomatic children. Symptomatic children often present with some degree of fatigue, fever, malaise, or infections. Physical examination frequently reveals pallor, easy bruising, and petechiae. Splenomegaly, hepatomegaly, and lymphadenopathy are uncommon findings. The peripheral blood cell counts usually reveal anemia, neutropenia, and thrombocytopenia.

Differential Diagnosis

With a careful history and physical examination, as well as the evaluation of peripheral blood and a bone marrow aspirate, biopsy, and cytogenetics, a diagnosis of MDS can be made. Severe nutritional deficiencies of vitamin B_{12} and folate should be excluded, because they may impart a megaloblastic appearance to the bone marrow. Other nutritional deficiencies such as thiamine, pyridoxine, iron, and riboflavin can also present as some degree of bone marrow dysplasia and should be considered in the differential diagnosis. Occasionally, severe aplastic anemia can be difficult to distinguish from MDS, although a bone marrow biopsy should resolve this question. Certain viral infections (e.g., human immunodeficiency virus, parvovirus B19, Epstein-Barr virus, human herpesvirus 6, cytomegalovirus) and exposures (e.g., irradiation, chemotherapy, organic solvents) are associated with bone marrow failure and should be considered before making the diagnosis of MDS. The bone marrow cell karyotype should be determined to identify any clonal abnormalities. In addition, evidence has suggested that whole-genome scan by SNP analysis may detect clonal abnormalities in some patients with a normal bone marrow cell karyotype.[982,983]

Treatment

The rarity and heterogeneity of MDS in children, the lack of consensus on nomenclature, and the need for a risk-based classification system specific for pediatric MDS have hindered the development of appropriate therapy for pediatric MDS. Most clinical trials studying MDS have enrolled adults, in whom the disease may be different, and there have been few meaningful trials enrolling children. Regardless of treatment, the overall clinical outcome of children with MDS is guarded.

The only proven curative treatment for MDS is allogeneic HSCT. AML-based chemotherapy without HSCT has resulted in poor survival in the 30% range.[984,985] Prior to HSCT, or if an appropriate donor was not available, treatment primarily consisted of supportive care with packed red blood cell or platelet transfusions, parenteral antibiotics, and hydration. Other noncytotoxic therapies, including hormone therapy (e.g., androgens, glucocorticoids), recombinant hematopoietic growth factors (e.g., G-CSF, GM-CSF, erythropoietin), and differentiating agents (e.g., 13-*cis*-retinoic acid, ATRA), have been used in adults and have shown minimal benefit.[986-996] Low-dose chemotherapy has been used in an attempt to promote differentiation of the malignant hematopoietic clone. Although studies using low-dose cytarabine have shown improvement in peripheral counts and decreased marrow blast percentages in some patients with MDS, the responses have not been sustained.[997] Other agents, such as melphalan, hydroxyurea, etoposide, topotecan, 6-mercaptopurine, and busulfan, have been used with only partial or temporary responses in small numbers of patients.

A number of new agents have emerged for the treatment of pediatric MDS after randomized clinical trials in adult patients. These therapies have evolved out of a growing interest in the field of epigenetics and the concept that the repression of key tumor suppressor genes in MDS may occur because of aberrant methylation and histone deacetylation, instead of or in concert with gene deletions and mutations.[252] Studies involving the *CDKN2B (p15*^{INK4B}*)* tumor suppressor gene have demonstrated evidence of methylated CpG islands in the promoter region, preventing gene transcription and leading to gene repression.[998,999] Since these initial studies, a number of other genes have been found to have reduced expression because of DNA methylation, thus prompting clinical trials of demethylating agents in MDS.[1000,1001] Based on the impressive response rates and delayed progression to AML compared with supportive care, two demethylating agents, 5-azacytidine and decitabine, have been approved by the FDA for the treatment of MDS in adults.[1002,1003] These agents have shown the greatest efficacy in low-risk MDS. They are given in a low-dosage schedule, and patients may need to be treated for several months before a clinical response is achieved. Although these agents have improved the time to progression in adult MDS, they cannot cure the disease. The role of these therapies in pediatric MDS is currently under active investigation. As indicated earlier, lenalidomide is now approved for the treatment of patients with MDS with the 5q− cytogenetic abnormality and appears to work best in those whose MDS clone lacks any other cytogenetic abnormalites.[937]

For children with MDS, allogeneic HSCT remains the treatment of choice. In the absence of a sibling donor, a matched unrelated donor should be sought. Children with lower-risk MDS are frequently treated with allogeneic HSCT without prior chemotherapy, particularly if a matched sibling is available, to avoid the need for large numbers of transfusions. In more advanced MDS (WHO RAEB1 and RAEB2), AML-type chemotherapy has been often administered to induce a remission or to reduce the disease burden before HSCT. A study from the Fred Hutchinson Cancer Research Center in Seattle in children with MDS demonstrated a 3-year survival rate of patients with lower-stage MDS of 74% compared with 68% for patients with more advanced disease.[1004] The European Working Group on MDS in Children (EWOG-MDS) reported a 55% 5-year EFS rate for 33 pediatric patients with MDS after HSCT.[1005] A recent pediatric study from the University of Minnesota demonstrated an OS of 53% and a DFS of 48% at 3 years for 37 pediatric patients with MDS who received allogeneic HSCT after myeloablative conditioning over a 20-year period ending in 2010. Earlier HSCT without preconditioning chemotherapy was associated with an improved outcome, suggesting that delaying transplant to reduce disease burden with AML-directed therapy is not warranted if an appropriate donor is available.[925] These results are in keeping with those found in a European study of pediatric MDS patients who received a myeloablative allogeneic HSCT in which the OS was 63% at 5 years.[984] This study similarly showed no benefit to pre-HSCT chemotherapy except for the group who had more advanced myelodysplasia-related AML, a subgroup not included in the prior study. A longer interval between diagnosis and HSCT was actually associated with less relapse but may have been confounded by the number of lower-risk MDS patients in this group.[984] TRM during transplant can be a significant issue, resulting in some groups attempting reduced-intensity conditioning regimens. These approaches have had variable success, with some studies reporting lower DFS rates.[925,1006]

MYELOPROLIFERATIVE DISORDERS

Juvenile Myelomonocytic Leukemia

JMML is a rare, clonal, myeloproliferative disorder of the stem cell that usually manifests in the first few years of life. It has also been referred to as juvenile chronic myelomonocytic leukemia (JCML), infantile monosomy 7 syndrome, or juvenile granulocytic leukemia. Although JMML, adult CML, and CMML have some similar features, JMML is a clinically and pathophysiologically distinct disorder of young children. An international consensus panel consisting of the JMML Working Group and the EWOG-MDS has established a set of clinical and laboratory criteria for the diagnosis of JMML (Box 51-3).[1007]

Box 51-3 **Recommended Diagnostic Criteria for Juvenile Myelomonocytic Leukemia**

CATEGORY 1 (ALL OF THE FOLLOWING)

No Philadelphia chromosome or BCR-ABL rearrangement
Peripheral blood monocyte count higher than 1000/μL
Bone marrow blasts less than 20%
Splenomegaly

CATEGORY 2 (AT LEAST ONE OF THE FOLLOWING)

Somatic mutations in *RAS*, *PTPN11*, or *CBL*
Clinical diagnosis of neurofibromatosis type 1 or *NF1* gene mutation
Monosomy 7

CATEGORY 3 (TWO OF THE FOLLOWING IF NO CRITERIA FROM CATEGORY 2)

Increased fetal hemoglobin level
Myeloid precursors in peripheral blood
White blood cell count greater than 10,000/μL
Clonal abnormalities (excluding monosomy 7)
Granulocyte-macrophage colony-stimulating factor hypersensitivity of myeloid progenitors in vitro

Modified from the World Health Organization criteria from the 2008 Juvenile Myelomonocytic Leukemia Symposium, Atlanta, Ga.

Pathobiology

The cause of JMML is unknown. Several recurrent chromosomal abnormalities have been associated with JMML, but their relevance to the pathogenesis of the disease is not well understood. For example, up to 20% of patients meeting the diagnostic criteria for JMML have abnormalities in chromosome 7 (e.g., monosomy 7, 7q−), and the genes involved and their contributions to disease pathogenesis remain an area of intense investigation.[540,1007] At the molecular level, one or more defects involving the NF1/RAS signal pathway have been demonstrated in studies of JMML cells, implicating this pathway in the development of the disease. Activating point mutations in *NRAS* and *KRAS* genes have been demonstrated in 15% to 30% of patients with JMML.[1008,1009] Other patients have loss of *NF1*, which codes for a RAS GTPase-activating protein involved in the GM-CSF signaling pathway.[68,1010] Mutations in *PTPN11* encoding the SHP-2 phosphatase have also been found in patients with JMML.[1011,1012] Similar *PTPN11* mutations have been found to cause Noonan syndrome, an autosomal dominantly inherited syndrome associated with short stature, cardiac abnormalities and characteristic facial features, and, occasionally, a JMML-like hematopoietic picture. More recently, studies using genome-wide SNP arrays have uncovered novel homozygous mutations in the E3 ubiquitin ligase gene, *CBL,* in patients with JMML without mutations in the other identified causative genes.[1013-1015] These mutations are all mutually exclusive. JMML cells grown in culture demonstrate a specific hypersensitivity to the growth factor GM-CSF that is not observed with other growth factors, such as interleukin-3.[1016] Knockout mice lacking expression of *NF1* die at embryonic day 13 or 14, but hematopoietic progenitor cells from these embryos grown in culture also demonstrate a specific hypersensitivity treatment with GM-CSF.[144] Moreover, immunodeficient mice transplanted with these cells develop a myeloproliferative disorder similar to JMML.[146,1017]

An increasing body of evidence has suggested that JMML arises from a pluripotent HSC, but the molecular abnormalities underlying the transformation appear to be distinct from those in the adult-type myeloproliferative disorders.[1017] JMML cells maintain their clonality when grown in long-term culture-initiating assays, in contrast to Philadelphia chromosome–positive CML cells, which yield to polyclonal residual normal cells in similar culture assays. Marrow cells from patients with JMML grow in culture and generate granulocyte-macrophage colony-forming units (GM-CFUs) spontaneously, in the absence of added hematopoietic growth factors. In contrast, GM-CFUs from normal individuals and from patients with adult CML only grow when exogenous growth factors are added to the semisolid culture medium.

Clinical Presentation and Prognosis

The presenting signs and symptoms of JMML result from organ infiltration of malignant cells; the most common symptoms are fever, cough, infection, pallor, malaise, hepatosplenomegaly, lymphadenopathy, rash, bleeding, and failure to thrive.[1007] Splenomegaly has now been incorporated as a category 1 criterion because only 7% of patients with JMML do not have splenomegaly at diagnosis.[1018] Laboratory abnormalities usually include an elevated WBC count with monocytosis, anemia, thrombocytopenia, an elevated fetal hemoglobin level, and hypergammaglobulinemia.[1007]

JMML is a progressive and often rapidly fatal disease, particularly in older children. Children younger than 2 years may have a more indolent course and, in fact, the disease may spontaneously resolve, as has been observed in patients with Noonan syndrome (reminiscent of TMD in Down syndrome) and a proportion of JMML patients with *RAS* or *CBL* mutations.[1018,1019] However, patients with older age at diagnosis (>2 years), higher fetal hemoglobin level, and platelets less than 33,000/μL tend to present with more complex cytogenetic abnormalities and are predisposed to poorer outcome.[1020] Although some studies have not found any prognostic differences in the genetic cause, others have found *PTPN11* mutations to be associated with increased relapse after HSCT.[1021] The accelerated blast phase characteristic of adult CMML is unusual in children with JMML.

Treatment

Several treatment regimens have been used to improve survival, including low-dose chemotherapy, intensive AML-type therapy, and 13-*cis*-retinoic acid.[540,1022-1027] Although durable remissions have been reported in a minority of cases, the response to these agents is usually transient and the long-term survival is poor. The only known curative therapy for JMML is allogeneic HSCT, and neither pretreatment chemotherapy nor splenectomy has not been found to impact survival.[1018] When an HLA-matched related donor is available, HSCT is the recommended treatment for patients with newly diagnosed disease. Survival rates of 35% to 55% have been reported with HSCT, but treatment-related mortality and relapse rates remain high, particularly for patients who undergo unrelated donor HSCT.[1028-1031] Several issues remain controversial, including the management of patients without HLA-matched related donors, GVHD prophylaxis, pre-HSCT chemotherapy, and appropriate myeloablative therapy. Future therapies in JMML are aimed at targeting downstream pathways from RAS, including mTOR- and PI3K-inhibiting agents.

Chronic Myelogenous Leukemia Caused by the *BCR-ABL* Fusion Gene

In 1951, Dameshek first introduced the idea that CML, polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PM) were related myeloproliferative syndromes, even though each has distinct clinical, laboratory, and biologic features.[1032,1033] A common feature is multilineage clonal proliferation involving the entire spectrum of myeloid cells, suggesting that transformation has occurred in a pluripotent stem cell. All these conditions, as well as systemic mastocytosis, hypereosinophilic syndrome, chronic eosinophilic leukemia, and chronic myelomonocytic leukemia, have been linked to a specific mutation or translocation resulting in the constitutive activation of a receptor tyrosine kinase. This accounts for the increased hematopoietic stem and progenitor cell proliferation with differentiation that characterizes these disorders. Patients may occasionally present with mixed manifestations rather than a distinct myeloproliferative disorder or, over the course of their illness, develop problems more typical of one of the other disorders.

Chronic myelogenous leukemia was first recognized as early as 1845, with several described cases of splenomegaly, anemia, and massive granulocytosis.[1034,1035] However, it was not until 1960, with the discovery of the Philadelphia chromosome, that the disease became better understood.[1036] CML constitutes 15% to 20% of all leukemias but accounts for only 1% to 3% of all childhood leukemias. In children, the disorder may present as one of two distinct clinical syndromes, adult-type CML (ACML), which is the same as the disease in older patients (and herein referred to as CML) and juvenile CML (JCML), now known as JMML, a syndrome described in the previous section that is restricted to children and has distinct clinical, laboratory, and cytogenetic characteristics (Table 51-2). The incidence of CML is less than 1 case/100,000 for patients younger than 20 years and 1 to 2 cases/100,000 for those 20 to 50 years, and it rises slowly thereafter. The median age at diagnosis is 67 years, and the male-to-female ratio is 1.8 : 1. It has been difficult to identify environmental factors associated with the pathogenesis of CML. Ionizing radiation is the only clearly identified risk factor for CML. A sevenfold increase has been documented in the survivors of the nuclear bomb–related exposure to radiation in Japan and, notably, the incidence of CML in this population was highest in young people, especially children younger than 5 years.[1037,1038]

Pathobiology

The diagnosis of CML is almost always associated with the t(9;22)(q34;q11) chromosomal translocation in bone marrow cells. This reciprocal translocation is detected by standard cytogenetic techniques in almost 90% of CML cases.[1036,1039] However, the presence of the Philadelphia chromosome in bone marrow cells is not pathognomonic for CML, because this chromosome is present at diagnosis in 25% to 50% of adult patients, 3% to 5% of children with ALL,[1040] and 2% of patients with AML. It is absent in 5% of patients with CML, although these patients' bone marrow cells may harbor a variant of the translocation detectable only by RT-PCR or FISH.[1041] The Philadelphia chromosome of CML involves a reciprocal translocation of the *ABL* gene from its normal position at the end of the q arm of chromosome 9 to a site on the q arm of chromosome 22 within the *bcr*

TABLE 51-2 Clinical Characteristics of Children with Juvenile Myelomonocytic Leukemia (JMML) versus Adult-Type Chronic Myelogenous Leukemia (CML)

Characteristics at Diagnosis	JMML	CML
Age (yr)	Usually <4	Usually >4
Lymphadenopathy	Common	Unusual
Skin lesions	Common	Unusual
Bleeding	Common	Unusual
Bacterial infection	Common	Unusual
White blood cell count >100,000/µL	Unusual	Common
Hemoglobin <12 g/dL	Common	Variable
Platelets	Usually decreased	Usually increased
Monocytosis	Common	Unusual
Circulating pronormoblasts	Common	Unusual
Increased fetal hemoglobin	Common	Unusual
Philadelphia chromosome	Absent	>90%
BCR-ABL fusion gene	Absent	Present
Leukocyte alkaline phosphatase decreased	Variable	Common
Clinical Course		
Median survival (yr)	1-2	Variable, >10 yr in chronic phase
Blast phase	Unusual	Common

region. The reciprocal t(9;22) chromosomal translocation creates a fusion *BCR-ABL* gene detectable in the bone marrow and peripheral blood by PCR assay. The chimeric gene encodes a dysregulated tyrosine kinase that is constitutively active, is expressed in the cytoplasm, and has increased activity compared with the normal ABL protein.[1042] In contrast to cytoplasmic BCR-ABL protein, normal ABL is a nuclear kinase, the activity of which is tightly regulated in vivo.[1043] Although the precise function of normal ABL is not known, available evidence suggests that it regulates pathways that mediate cell cycle arrest after genotoxic damage.[1044-1048] The main clinical manifestation of CML is an overabundance of mature myeloid cells from hyperproliferative progenitor cells. Evidence for the role of the *BCR-ABL* translocation in the pathogenesis of CML is confirmed by the observation that BCR-ABL proteins can also induce a CML-like syndrome in vivo in mice when they are expressed in hematopoietic progenitors.[1049-1052] Mechanistic studies of these fusion proteins have shown that RAS signaling is essential for transformation and that multiple accessory molecules, including the adapters GRB2, SHC, and CRKL, are used to couple the activated ABL kinase to RAS, resulting in activation of Jun kinase.[1053-1055] Oncogenic signaling by BCR-ABL has also been shown to involve the cell cycle–regulated genes *MYC* and *cyclin D1*.[1056,1057] Thus, multiple signaling pathways are activated to mediate leukemic transformation by BCR-ABL. Transformation has also been shown to occur in the pluripotent stem cell. Murine experiments in which sorted HSCs were transduced with *BCR-ABL* and transplanted into irradiated recipients developed a CML-like phenotype, whereas the same experiment performed using more differentiated progenitor cells failed to induce a myeloproliferative disease.[111] Moreover, granulocytes, monocytes, erythroid cells, megakaryocytes, and lymphocytes from patients with this disease have been shown to be clonal progeny of a single cell and to harbor the Philadelphia chromosome.[1058-1060] Probably because of some persistent normal hematopoiesis in patients with CML and because of the long life span of some cell types, such as T lymphocytes, all patients do not have demonstrable involvement of all lineages.[1059] It is worth emphasizing that the *BCR-ABL* fusion gene is acquired somatically by an HSC and its expression is restricted to its clonal progeny, so the nonhematopoietic cells of the patient do not contain the translocation.[1061,1062]

Clinical Presentation

CML can present in one of three phases—chronic phase, accelerated phase, or blast crisis. Most patients present in the chronic phase and may be asymptomatic. When symptoms and signs are present, they are often mild and are caused by the accumulation of mature and immature granulocytic cells. Generalized malaise, weakness, weight loss, fever, pallor, and organomegaly, particularly splenomegaly, are frequent presenting symptoms. Abdominal pain from massive splenomegaly may also bring a patient to medical attention. CNS, retinal, and pulmonary dysfunction can occur, as well as arthritis and priapism. Occasionally, the diagnosis is made from a routine blood cell count.[1063] WBC counts usually exceed 100,000/µL, with the appearance of some circulating immature myeloid forms.[1064,1065] Basophilia and eosinophilia may also occur. In addition, platelet counts above 400,000/µL are frequently observed, although thrombocytopenia may also occur. The WBC and platelet counts in CML patients may fluctuate spontaneously and nonconcordantly, making it difficult to attribute changes to the effects of therapy.[1066] The presence of anemia is also variable in CML.[1067] Leukostasis, a syndrome caused by hyperleukocytosis and frequently presenting as neurologic symptoms, such as dizziness, confusion, and somnolence, or pulmonary symptoms, including tachypnea, dyspnea, and respiratory failure, is observed in AML and ALL secondary to high blast cell counts. However, symptoms of leukostasis are uncommon in adults with CML and are only slightly more common in childhood CML, even in patients with very elevated WBC counts.[1068] Skin nodules, representing extramedullary hematopoiesis, may also be present.[1069] The bone marrow in CML patients typically demonstrates normal myeloid maturation, with granulocytic hyperplasia and an increased myeloid-to-erythroid ratio. Megakaryocytic hyperplasia may also occur.[1063]

Dysplastic marrow basophils or eosinophils are common, and cells of these lineages may be increased in number. About one in six CML patients has lipid-laden macrophages, sometimes called sea-blue histiocytes, similar to Gaucher cells.[1070] Although an increase in reticulin may occur, myelofibrosis is unusual. By definition, in chronic phase CML, the blast cell percentages in both the peripheral blood and bone marrow are less than 10%, and an increase above these levels may indicate a transition from chronic phase to accelerated phase or blast crisis. Other abnormal laboratory findings in chronic phase CML include low leukocyte alkaline phosphatase (LAP) activity and increased vitamin B_{12} levels. The latter occurs because of the increased white blood cell mass, which produces WBC-derived vitamin B_{12}–binding protein. The cause of the low LAP is unclear but may involve imperfect maturation of CML granulocytes. With therapy, the level of vitamin B_{12} falls to normal, whereas changes in LAP are less predictable.[1071]

The accelerated phase is characterized by increased marrow or blood blast cell values of 10% to 19%, peripheral basophilia greater than 20%, persistent thrombocytopenia unrelated to therapy or thrombocytosis unresponsive to therapy, and increasing spleen size or WBC count. If marrow or blood blast cell percentages exceed 19% of total leukocytes, this signifies a transition to blast crisis, which may be myeloid, lymphoid, or mixed. Presentation in blast crisis can mimic an acute leukemia of lymphoid or myeloid lineage, and in this case the cells harbor the Philadelphia chromosome.

Differential Diagnosis

The differential diagnosis of an elevated WBC count (also known as a leukemoid reaction) includes severe infections, congenital heart disease, and metastatic cancer. In disorders other than CML, the peripheral blood rarely contains blasts and promyelocytes, the WBC count is usually somewhat lower, and the LAP scores and cytogenetic studies are normal. In general, patients with CML have a WBC count of more than 100,000/μL, a WBC differential containing promyelocytes and myelocytes (the blood smear often appears similar to a marrow smear), a low LAP, a large spleen, and Philadelphia chromosome or molecular detection of the *BCR-ABL* transcript. Because CML patients can present in blast crisis, the patient with Philadelphia chromosome–positive ALL presents a problem in differential diagnosis. Determination of the size of the abnormal fusion protein (usually 210 kD in CML and 185 kD in Philadelphia chromosome–positive ALL) and the fusion transcript breakpoint by RT-PCR assay can help, as can the response to therapy. An important distinction is that in ALL the Philadelphia chromosome commonly disappears with intensive chemotherapy whereas in CML presenting in blast crisis the disease may revert to the chronic phase, with the Philadelphia chromosome persisting in the recovering bone marrow cells.[1072]

Clinical Course

Approximately 90% of patients are in the chronic phase at diagnosis. Prior to the advent of tyrosine kinase inhibitor therapy, patients sometimes enjoyed unimpaired lifestyles for periods of many months to years, with minimal therapy during the chronic phase of their disease. However, if untreated, most patients will experience progressive disease from 3 to 8 years after diagnosis. This is because of the development of the accelerated phase, which progresses to eventual blast crisis, usually within 3 months. Overall, blast crisis will develop in 75% to 85% of all untreated patients with CML. Blast crisis is a clinically high-risk form of CML that is difficult to control with chemotherapy and often leads to death within a short time, usually months.

Although BCR-ABL alone may be able to induce chronic-phase CML, evolution to accelerated phase or blast crisis is often accompanied by the acquisition of duplicated Philadelphia chromosome or additional cytogenetic abnormalities in the bone marrow, such as trisomy 8 or abnormalities involving chromosome 7, including the t7;11(p15;p15) that creates the *NUP98-HOXA9* fusion.[1073] Transformation to blast crisis appears to follow many of the same multiple mutational steps involved in the molecular pathogenesis of de novo AML or ALL. LAP levels may also rise during the transition to blast crisis. Myeloid blast crisis is somewhat more common and carries a poorer prognosis than lymphoid blast crisis.[1072,1074-1076] About one third of patients have a lymphoblastic crisis, usually precursor B-cell by immunophenotype, although T-lymphoblastic crisis phenotypes can occur.[1077,1078] Patients with lymphoid blast crisis have a younger median age than patients with myeloid blast crisis.[1079] CML blast crisis can also contain subpopulations of blast cells with differing phenotypes (possibly subclones differentiated along both lymphoid and myeloid lineages, biphenotypic leukemias) and blast crisis in which individual cells simultaneously express features of more than one lineage (mixed-lineage leukemias).

Treatment

Historic Chemotherapy. Traditional chemotherapy for CML used busulfan or hydroxyurea.[1080] Busulfan is associated with infertility and, rarely, marrow aplasia and interstitial pneumonitis. Hydroxyurea is less toxic but only induces a decreased granulocyte count. Hydroxyurea does not induce cytogenetic remissions or change the natural history of the disease. Interferon-α (IFN-α) has demonstrated improved rates of hematologic remission over hydroxyurea, with evidence of hematologic control in 70% to 80% of patients and complete cytogenetic responses in 6% to 26% when given as a single agent in different series.[1081-1083] The normalization of bone marrow cytogenetics was shown to persist for many years in some patients, even after stopping the drug. Interestingly, these patients often remain PCR positive for the *BCR-ABL* transcript if sensitive techniques are used.[1084-1086] Despite the efficacy of IFN-α, unwanted side effects are common and include fatigue, myalgias, arthralgias, headaches, weight loss, depression, diarrhea, neurologic symptoms, memory changes, hair thinning, autoimmune diseases, and cardiomyopathy,[1087-1089] leading 14% to 26% of patients to discontinue therapy.[1090-1093] Thus although IFN-α demonstrated some promise in this disease, the toxicity profile made it intolerable to a large fraction of CML patients.

Tyrosine Kinase Inhibitors. The treatment of chronic phase CML has since been revolutionized with the advent of molecularly targeted therapy that specifically targets the BCR-ABL fusion protein. Imatinib mesylate, also known as STI-571 or Gleevec, is a tyrosine kinase inhibitor that blocks enzymatic activity of several tyrosine kinases, including mainly ABL, PDGFR, and KIT, by binding to the adenosine triphosphate (ATP) binding site. The promising results of phase I and II studies that produced impressive activity in patients who had already failed IFN-α[1094] led to the International Randomized Study of Interferon and STI571 (IRIS), which randomized patients to imatinib versus interferon with cytarabine as initial therapy for patients with CML.[1095] This study demonstrated better outcome with longer times to progression and to accelerated phase or blast crisis for patients initially treated with imatinib. Additionally, patients treated with imatinib had higher rates of hematologic and cytogenetic remission and, for the first time, molecular responses were obtained with an undetectable *BCR-ABL* fusion transcript. Treatment with imatinib effectively established new standards for response rates, including complete hematologic response (CHR), implying a normalization of peripheral blood cell counts; major cytogenetic response (MCyR), with the presence of Philadelphia chromosome in 1% to 35% bone marrow cells analyzed by metaphase spread; complete cytogenetic response (CCyR), with the absence of Philadelphia chromosome; and major molecular response (MMR), demonstrating a 3-log reduction in detection of the *BCR-ABL* transcript in bone marrow cell RNA compared with diagnostic levels. The 8-year follow-up of the IRIS study has now been published[1125] and has convincingly demonstrated the long-term benefit and tolerability of imatinib therapy, with increasing rates of MMR and CCyR over time. Imatinib has excellent oral bioavailability, with minimal systemic effects other than myelosuppression. Other side effects include peripheral and periorbital edema, muscle cramps, gastrointestinal intolerance, and rash. Cardiac complications, including congestive heart failure, are rare but have been reported.[1097] However, imatinib must be continued indefinitely because cessation of the drug is generally associated with an increase in bone marrow cell *BCR-ABL* transcript levels and, eventually, hematologic relapse. Given the success of imatinib therapy, a number of studies have strived to determine what cytogenetic or molecular milestones at what specific time points after initiation of imatinib are most predictive of response. CCyR is regarded as the gold standard and considered to correlate with a 2-log reduction of *BCR-ABL* transcript levels (expressed as 1% on the recently accepted international scale that establishes 100% as an initial transcript level). A recent study demonstrated that a transcript level of less than 10% at the 3-month mark had the greatest prognostic value in predicting outcome.[1098] Although current practice includes surveillance at later time points, this manuscript provocatively suggests that changes in management can effectively be made at this early juncture and may preclude the need for further evaluations including invasive bone marrow evaluations. However, the counter argument is that bone marrow evaluations are important for examination of new collaborating cytogenetic abnormalities that may herald the evolution of a clonal population and accelerated disease.

Based on the success, promise, and safety profile of imatinib therapy in adults, studies to determine the efficacy of this drug in childhood CML have been undertaken. The COG published the results of a phase I trial of imatinib in children with Philadelphia chromosome–positive disease who had failed interferon therapy.[1099] Imatinib was well tolerated at escalating dose levels up to 570 mg/m^2 and CHR was demonstrated for all 14 chronic-phase patients within 1 month of starting therapy. Ten of 12 evaluated patients had achieved a CCyR by a median of 3 months. A phase II European pediatric study[1100] demonstrated equally encouraging results for children with chronic-phase CML who failed IFN-α therapy. These studies and extrapolation from adult data have resulted in imatinib becoming first-line therapy in children with chronic-phase CML. Confidence in this approach has been improved by evidence that prior imatinib therapy has no negative impact on the TRM after an allogeneic donor HSCT.[1101] Side effects of imatinib in children include gastrointestinal problems and rashes. If signs of leukostasis are present, more urgent therapy must be used. If the WBC count must be lowered quickly, leukapheresis and immediate chemotherapy with high-doses of hydroxyurea may be used. Proper hydration, alkalinization of the urine, and the use of allopurinol are imperative before the rapid lysis of cells is induced with chemotherapy.

Resistance to imatinib mesylate has been demonstrated.[1102-1106] Mechanisms of resistance include point mutations in *BCR-ABL*, amplification of the *BCR-ABL* gene, overexpression of the BCR-ABL protein, enhanced expression of the multidrug resistance gene, and excessive binding of imatinib by serum proteins. Analysis of a small number of blast crisis patients who experienced relapse while receiving imatinib has frequently shown either *BCR-ABL* gene amplification or *BCR-ABL* kinase domain mutations.[1103] These observations have indicated that resistance to imatinib as a single agent in the treatment of CML involves alterations of the BCR-ABL protein expression level or structure, allowing it to escape inhibition by the drug, rather than mutations in entirely different genes that might have reduced the malignant cells' dependence on BCR-ABL for transformation. A number of approaches have been suggested as interventions after the identification of imatinib resistance. High-dose imatinib has shown some promise for inducing cytogenetic remissions, despite a lack of efficacy of standard-dose therapy.[1107] Additionally, a number of new tyrosine kinase inhibitors have emerged and are more potent inhibitors of BCR-ABL than imatinib. Nilotinib is a structural derivative of imatinib and effective at lower concentrations.[1108] At doses of 300 mg to 400 mg twice daily, it is well tolerated in adults,[1108a] although it requires fasting before and after each dose, a requirement that potentially complicates its administration to children. Dasatinib has a completely different structure and binding configuration, making it active against most imatinib-resistant *BCR-ABL* mutations, as well as a host of other tyrosine kinases. Dasatinib has a higher incidence of thrombocytopenia than imatinib and is associated with a high incidence of pleural effusions in adult patients. Both dasatinib and nilotinib are FDA approved for the treatment of imatinib-resistant chronic-phase CML.[1107,1109,1110] More recently, head-to-head randomized control trials in adult patients with chronic-phase CML have demonstrated that both of these agents are more effective as frontline therapy at achieving CCYR by 1 year than imatinib.[1111,1112] The COG recently completed a phase I trial of dasatinib for imatinib-resistant leukemia and solid tumors. Nine CML patients who had experienced relapse were included and generally tolerated doses as high as 85 mg/m^2; there was one case of hemangiomatosis, and cytogenetic responses were demonstrated in 5 patients (complete response in 3 and partial response in 2).[1113] These results have prompted studies in newly diagnosed patients with Philadelphia chromosome–positive ALL, combining dasatinib in doses of 60 mg/m^2 with intensive chemotherapy and a proposed COG study for dasatinib as a frontline agent in CML. Nilotinib is now being considered for a phase II study in pediatric CML resistant to imatinib or dasatinib.

Hematopoietic Stem Cell Transplantation. Of all malignancies, CML has the most extensive long-term data on the effectiveness of allogeneic HSCT. This approach can provide prolonged DFS in CML and is the only proven curative therapy. The effectiveness of allogeneic HSCT in CML is believed to be caused in part by the effects of the transplanted immune system, rather than solely the result of the high-dose total-body irradiation and chemotherapy in the conditioning regimen. The allogeneic graft creates a new immune system that plays an active role in eradicating CML cells. Immune-mediated antileukemic effects are suspected because patients may remain PCR positive for *BCR-ABL* transcripts for months after HSCT and yet appear to be cured of their disease and eventually convert to PCR negativity without further therapy. Furthermore, there is an extremely high relapse rate for autologous, syngeneic, and T-cell–depleted grafts with the same myeloablative conditioning regimens used for standard, non–T-cell–depleted grafts, a result that suggests alloreactivity is associated with lower relapse rates.[1114-1116]

The role of allogeneic HSCT in CML provides a moving target in the post–tyrosine kinase inhibitor era. The potential toxicity associated with allogeneic HSCT, especially from a matched unrelated donor, compared with the efficacy and tolerability of oral tyrosine kinase inhibitors has raised questions regarding the indications and timing for HSCT in CML patients. Although some patients may go on to long-term survival when HSCT is performed in accelerated phase or blast crisis of CML (15% to 30% of cases), results are substantially better when HSCT is performed in the chronic phase.[1117] If the procedure is performed while the patient is in chronic phase using a matched sibling donor, 1-year survival rates are 60% to 80%, with a 10-year DFS rate of approximately 50%.[1114,1118-1120] Some studies have demonstrated increased survival outcomes if the HSCT was performed within the first year of diagnosis.[1121-1123] Prior to imatinib therapy, these data prompted the initiation of allogeneic HSCT early in the course of treatment. However, HSCT has always been limited to patients who can medically tolerate the procedure and have appropriate donors—30% have matched sibling donors, 5% have matches with additional family members, and 50% have matched unrelated donors in donor registries. Imatinib can be safely given pre-HSCT and has no impact on TRM.[1101,1124] Currently, most adult patients, including even those with sibling donors, are being maintained on imatinib until evidence of resistance develops, which then prompts a change in therapy and consideration of HSCT. In children, the timing of HSCT for CML is even more challenging. Although imatinib has now demonstrated impressive 8-year outcomes,[1125] will these be sustained for the many years that a child with CML would be required to take the drug? Allogeneic HSCT still remains the only curative therapy and is generally better tolerated by children, particularly with modern approaches to supportive care.

Between 10% and 15% of recipients of matched sibling HSCT and less than 5% of matched unrelated donor recipients experience relapse hematologically after allogeneic HSCT. Patients who experience relapse after HSCT may respond to interferon or withdrawal of immunosuppression.[1126-1129] Recent evidence has suggested that relapse rates may be reduced with the addition of imatinib therapy after HSCT whether or not the patient received imatinib before HSCT. However, the recommended duration of imatinib therapy after HSCT remains uncertain. Patients who experience relapse after HSCT may benefit from a second-generation tyrosine kinase inhibitor, such as dasatinib, a second HSCT, or donor-lymphocyte infusions. Sixty to 80 percent of patients who experience relapse cytogenetically or hematologically and return to chronic phase after HSCT can be salvaged by donor lymphocyte infusions without further cytotoxic chemotherapy.[674,1130-1132] Unfortunately, acute and chronic GVHD and marrow aplasia remain significant complications after donor lymphocyte infusion.[1133] Relapse occurs again in 5% to 15% of patients successfully treated with donor lymphocyte infusion, but remissions induced by this modality are durable in most patients.

Blast-Phase Chronic Myelogenous Leukemia

Blast-phase CML is generally resistant to chemotherapy.[1074] As in acute leukemia, leukostasis is more likely in patients with high blast counts, and rapid institution of therapy to lower the WBC count is indicated after initiating measures to protect the patient from tumor lysis syndrome. The blast cell morphology and surface markers should guide therapy in blast crisis of CML. Lymphoid blast morphology or surface markers predict a good initial response to drugs effective in ALL, such as prednisone and vincristine.[1063,1079,1134] However, patients whose blast cells have a myeloid morphology and immunophenotype respond poorly to most therapies. Median survival is only 2 months after transformation to myeloid blast crisis, compared with 6 months if the blast cells have lymphoblastic characteristics.[1135] Allogeneic HSCT in late-stage CML is associated with a poor outcome, primarily because of the high peri-HSCT mortality from regimen-related toxicity and an extremely high relapse rate.

Chronic Myelogenous Leukemia Caused by Other Translocations

Other chromosomal translocations have also been identified in CML. The *TEL* gene belongs to a large family of transcription factors referred to as the *ETS* family. These genes encode related proteins defined by a highly conserved, 90-amino acid, winged helix-turn-helix dimerization motif. This region appears to be an essential requirement for constitutive tyrosine kinase activity and transforming capacity of fusion proteins derived from chromosomal translocations involving *TEL*, generally partnered with a tyrosine kinase gene such as the *PDGF* receptor.[1136-1138] With the exception of the t(12;21)-associated *TEL-AML1* fusion gene exclusively associated with early B-cell lineage ALL, *TEL* gene rearrangements are rare in human leukemia. Because of the small numbers of patients with myeloid malignancy who have *TEL* gene fusions, there is insufficient clinical experience to determine their clinical implications. However, there is a trend toward an unfavorable outcome in patients with atypical CML or CMML accompanied by *TEL* gene rearrangements.

Polycythemia Vera

Polycythemia is defined as an increase in numbers of circulating erythrocytes, hemoglobin, and hematocrit. There are three types of polycythemia: (1) polycythemia vera (PV), or primary polycythemia; (2) secondary polycythemia; and (3) relative polycythemia.[1139] The first two types are associated with an increase in red blood cell mass, whereas in the third the red blood cell mass is normal and plasma volume is reduced. Secondary polycythemia can arise from a multitude of causes, including those that result in excessive erythropoietin production caused by decreased tissue oxygenation (physiologically appropriate), inappropriate erythropoietin secretion from a tumor, a mutant hemoglobin with abnormal oxygen affinity, and decreased erythrocyte diphosphoglycerate.

PV is a myeloproliferative disease caused by clonal expansion of an abnormal multipotent stem cell that produces erythroid progenitors that can proliferate in the absence of erythropoietin (EPO).[1140,1141] In contrast, normal fetal erythroid progenitors and those with mutations in the EPO receptor still require erythropoietin for their function. Growth of erythropoietin-independent erythroid colonies in serum-containing cultures can be a useful diagnostic test.[1141] Because this is an HSC disorder, aberrations in the WBC and platelet counts can accompany the increased red blood cell mass. The diagnosis of PV used to be a diagnosis of exclusion. One had to prove that the elevated red cell mass was not from a secondary cause, such as hypoxia or a high oxygen affinity hemoglobin, and that the *BCR-ABL* transgene was absent. However, in 2005, several groups simultaneously reported the presence of a somatically acquired clonal *V617F* mutation in *JAK2* in more than 90% of cases of sporadic PV in adults.[1142-1145] This seminal discovery linked PV with the other myeloproliferative disorders, such as CML, by demonstrating a primary mutation in a tyrosine kinase as a causative factor and effectively established *JAK2* mutational analysis as a diagnostic test for PV. Interestingly, this same mutation was found in 50% of cases of essential thrombocythemia (ET; see later) and primary myelofibrosis (PM).[1142-1145] These three different phenotypes caused by the same genotype pose many questions, and scientists are currently investigating the role of gene dosage, modifying mutations, or genetic predisposition to account for the difference in disease phenotype. Some studies have suggested that patients with PV have at least a subpopulation of cells that are homozygous for the *JAK2* mutation whereas patients with ET are heterozygous.[1146,1147] Moreover, the *JAK2* mutation may be sufficient to induce PV but other mutations are likely required for the development of ET and PM. Rare cases of familial polycythemia may exhibit autosomal recessive or dominant inheritance, and erythropoietin levels can be low, normal, or elevated.[1148] Studies of these families have revealed that the *JAK2* mutation is acquired, suggesting that there is an inherited predisposition allele that has not yet been identified.[1149] In some of the families, a mutation in the negative regulatory domain of the erythropoietin receptor gene appears to be involved.[1150-1152] Several *JAK2-V617F*–negative patients with PV were found to have a number of different mutations involving exon 12 of *JAK2*.[1153]

The WHO previously established strict criteria for the diagnosis of PV, with recent suggestions for revisions to *JAK2* mutational evaluation.[1154-1156] Evaluation should include a careful history and physical examination, including examination for splenomegaly and measurements of oxygen saturation, a complete blood cell count, and serum erythropoietin level, *JAK2* mutational analysis, and bone marrow aspirate and biopsy, including cytogenetics to rule out *BCR-ABL* or other translocation-induced fusion genes.

PV is extremely uncommon in children. The median age at presentation is 60 years, and fewer than 1% of PV patients are younger than 25 years.[1139,1157,1158] Children with PV are also less likely than adults to exhibit the most prevalent *JAK2* mutation. Erythrocytosis can cause cardiac symptoms, such as dyspnea and hypertension, and symptoms of disturbed cerebral circulation, such as dizziness and paresthesias. Abnormal platelet function and thrombocytosis may lead to thrombosis and hemorrhage. Granulocytic proliferation can cause increased histamine turnover, resulting in gastrointestinal symptoms and pruritus. Hyperuricemia and hypermetabolic symptoms are common, including weakness and weight loss. Most patients have large spleens and may have large livers and increased blood pressure.[1139] The marrow shows hypercellularity, an increase in megakaryocyte number, and decreased iron stores. Serum erythropoietin levels are usually normal or decreased.[1159] A total of 10% to 25% of patients have a clonal chromosomal abnormality evident by cytogenetic analysis, most often a

Box 51-4 **Suggested Criteria for Childhood Polycythemia Vera***

MAJOR CRITERIA

Increased hemoglobin/hematocrit
Presence of *JAK2-V617F* mutation
No cause of secondary erythrocytosis, including:
- a. Absence of familial erythrocytosis (e.g., hereditary mutations of erythropoietin [EPO] receptor)
- b. No elevation of EPO caused by
  - i. Hypoxia (PaO_2 <92%)
  - ii. High oxygen affinity hemoglobin
  - iii. Truncated EPO receptor
  - iv. Inappropriate EPO production by tumor

MINOR CRITERIA

Spontaneous erythroid colony formation
Hypercellular bone marrow with trilineage proliferation
Low serum EPO levels

Modified from Vardiman JW, Harris NL, Brunning RD: The World Health Organization (WHO) classification of the myeloid neoplasms. Blood *100:2292–2302, 2002; Tefferi A, Thiele J, Orazi A, et al: Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: recommendations from an ad hoc international expert panel.* Blood *110:1092–1097, 2007; Teofili L, Giona F, Martini M, et al: Markers of myeloproliferative diseases in childhood polycythemia vera and essential thrombocythemia.* J Clin Oncol *25:1048–1053, 2007; Teofili L, Giona F, Martini M, et al: The revised WHO diagnostic criteria for Ph-negative myeloproliferative diseases are not appropriate for the diagnostic screening of childhood polycythemia vera and essential thrombocythemia.* Blood *110:3384–3386, 2007; and Barbui T. How to manage children and young adults with myeloproliferative neoplasms.* Leukemia *26:1452–1457, 2012.*

*Requires the presence of both major and one minor criteria or two to three minor criteria in the absence of the *JAK2* mutation.

20q– deletion. Box 51-4 lists suggested criteria for the diagnosis of pediatric PV.[1160,1161]

Prolonged survival after the diagnosis of PV is common, but spontaneous remission is rare.[1162] Vascular occlusive episodes related to high hematocrit levels are an important cause of morbidity and mortality, with Budd-Chiari syndrome being among the most common manifestations.[1163] Other life-threatening complications of polycythemia vera include bleeding, myelofibrosis with pancytopenia, and acute leukemia.[1164] A poorly defined spent phase may occur, characterized by a decrease in hematocrit (often because of increased plasma volume), variable depression of other blood cell counts, hepatosplenomegaly, and increased bone marrow reticulin and fibrosis.[1165,1166] The decision to treat children with PV who are otherwise asymptomatic is controversial, given the potential side effects and complications of the various therapeutic options. Some experts advocate for completing a thrombophilic workup to assist in determining factors that might contribute to the risk for developing significant thrombi and shift the risk-benefit balance in the direction of treatment.[1167,1168] Treatment includes phlebotomy, although isovolumic erythropheresis may be a safer procedure, but this requires specific resources and is not uniformly available.[1169] The highest risk for thrombotic or hemorrhagic complications is observed immediately after phlebotomy. Iron replacement therapy should be given, because iron deficiency can lead to nonhematologic disturbances and an increase in blood viscosity.[1170] Low-dose aspirin is also recommended for adults with PV and has been adopted in the prophylaxis of thrombosis in children with PV.[1168,1171] Radioactive phosphorus or chemotherapy can also control the hematocrit in PV. However, these treatments have been associated with an increased risk for transformation to AML.[1164] Hydroxyurea, IFN-α, and anagrelide are all agents used in adults to control cell counts and may be useful in pediatric cases.[1172-1174] Hydroxyurea is simpler to administer and has fewer side effects than IFN-α, and the leukemogenic risk of hydroxyurea appears to be low, as demonstrated by a number of long-term studies in sickle cell anemia patients. However, the risk for transformation to AML is still higher in PV, because patients have a primary clonal stem cell disorder.[1175] The main toxicity from hydroxyurea is neutropenia. Anagrelide is a newer agent that inhibits the action of cyclic AMP phosphodiesterase and primarily targets megakaryocyte differentiation and proliferation. It has resulted in the disappearance of thrombocythemia-related symptoms in 80% of patients with PV.[1176] However, it has been found to be inferior to hydroxyurea in ET.[1177] Given their familiarity and experience with the agent, most clinicians would use hydroxyurea in children with PV deemed at higher risk for thrombosis, owing to extremely elevated hematocrit or prior thrombotic event or bleeding, due to features such as esophageal varices, which could be exacerbated by phlebotomy or therapy with acetylsalicylic acid. IFN-α, particularly newer pegylated versions, is both effective and better tolerated[366,1168] and thus a reasonable alternative. A number of JAK2- and combined JAK1/JAK2-inhibiting agents have been developed and have demonstrated some symptom relieve in PM (see later) but have not proven to be more effective than hydroxyurea, IFN-α, and anagrelide in PV.[1178,1179]

Essential Thrombocythemia

ET is a myeloproliferative disorder characterized by an increased platelet count not attributable to any other cause; Box 51-5 lists causes of thrombocytosis.[1157,1180-1184] Similar to the other myeloproliferative diseases, ET is a clonal stem cell disorder that also affects other hematopoietic lineages.[1185] The *JAK2 V617F* mutation is found in approximately 50% of cases, and other cases may be associated with a mutation affecting the genes encoding thrombopoietin or the thrombopoietin receptor (MPL).[1186-1188] ET may occur in childhood, but rarely,[1158,1186,1189-1191] and it may be familial in some cases.[1192] A number of families have been identified who have ET and/or other myeloproliferative diseases with or without acquisition of the *JAK2-V617F* mutation, demonstrating that other mutations are involved in the pathogenesis of the disease and that there is likely an underlying genetic predisposition that has not yet been elucidated.[1149,1193,1194] The requirements for ET are a platelet count greater than 450,000/μL (previously 600,000/μL), a hemoglobin concentration not exceeding 13 g/dL (normal red blood cell mass), normal iron stores, a lack of the Philadelphia chromosome by molecular or cytogenetic analysis, the absence of collagen

fibrosis of the marrow, and no other identifiable cause of thrombocytosis.[1156,1180] Box 51-6 suggests criteria for the diagnosis of pediatric ET.

ET may be an incidental finding, or patients may present with venous or arterial thrombosis, bleeding, or symptoms of a hypermetabolic state. The bleeding is generally mild, and its cause is unknown, although platelet function is often abnormal.[1195,1196] Splenomegaly is common, as is mild leukocytosis. Bone marrow cytogenetics are usually normal. The clinical course is highly variable, and some patients have been followed up for 10 years without problems.[1184] In adults, 80% survive more than 100 months, with 5 of 95 patients ultimately experiencing a conversion to AML in one study.[1197] Patients with ET can also develop myelofibrosis. Children appear to have a more benign course than adults.[1158,1186,1198] Asymptomatic children do not need to be treated. Treatment options are similar to those available for PV, including hydroxyurea, anagrelide,[1199-1201] or IFN-α.[1202,1203] Treatment is usually recommended to prevent thrombotic complications in patients with platelet counts higher than 1 million/μL or a prior history of thrombohemorrhagic episodes. Hemorrhage may paradoxically occur with these very high platelet counts as a result of an acquired von Willebrand disease.[1204,1205] A randomized clinical trial in adults of hydroxyurea and acetylsalicylic acid or anagrelide and acetylsalicylic acid has demonstrated equal efficacy of these combinations in lowering the platelet count but a higher incidence of arterial thromboses, significant hemorrhage, and transformation to myelofibrosis in the anagrelide-treated group.[1177] More recently, evaluation by the European LeukemiaNet revealed that although anagrelide increased response rates it did not impact OS.[1206] These results suggest that hydroxyurea should serve as frontline therapy, particularly because the theoretical risk for malignant transformation has not been seen.[366,1168] Acetylsalicylic acid has previously been considered to have value in primary prophylaxis for thrombosis, but its utility was called into question in a recent study demonstrating a preventative benefit only in patients with predisposing thrombotic risk factors (*JAK2* mutation or cardiovascular risk factors), where it otherwise increased bleeding risk.[1207] Thus prolonged use of acetylsalicylic acid may be falling out of favor for asymptomatic patients with ET.

Primary Myelofibrosis

PM is a myeloproliferative disease characterized by leukoerythroblastosis, myeloid metaplasia, and varying degrees of myelofibrosis.[1208-1210] The median age at

Box 51-6 Suggested Criteria for Childhood Essential Thrombocythemia

Sustained platelet count greater than 450,000/μL
Bone marrow biopsy specimen showing proliferation mainly of the megakaryocytic lineage, with increased numbers of enlarged mature megakaryocytes; no significant increase or left shift of neutrophil granulopoiesis or erythropoiesis
Not meeting World Health Organization criteria for polycythemia vera, primary myelofibrosis, chronic myelogenous leukemia, myelodysplastic syndrome, or other myeloid neoplasm (e.g., no Philadelphia chromosome or *BCR-ABL* fusion)
Demonstration of *JAK2-V617F* or of another clonal marker (e.g., *MPL* mutation) or, in the absence of a clonal marker, no evidence of reactive thrombocytosis

Modified from Vardiman JW, Harris NL, Brunning RD: The World Health Organization (WHO) classification of the myeloid neoplasms. Blood *100:2292–2302, 2002; Tefferi A, Thiele J, Orazi A, et al: Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis:* recommendations *from an ad hoc international expert panel.* Blood *110:1092–1097, 2007; Teofili L, Giona F, Martini M, et al: Markers of myeloproliferative diseases in childhood polycythemia vera and essential thrombocythemia.* J Clin Oncol *25:1048–1053, 2007; and Teofili L, Giona F, Martini M, et al: The revised WHO diagnostic criteria for Ph-negative myeloproliferative diseases are not appropriate for the diagnostic screening of childhood polycythemia vera and essential thrombocythemia.* Blood *110:3384–3386, 2007.*

presentation is 60 years, and pediatric cases are rare.[1211] Approximately 22% of patients are younger than 56 years, and approximately 11% are younger than 46 years.[1212] Fewer than 100 cases have been reported in children, and many of these are in patients younger than age 3 years.[1168] Symptoms may include malaise, weight loss, night sweats, and discomfort from splenomegaly. Peripheral blood cell counts are varied, and the smears often show Pelger-Huët cells, leukoerythroblastosis, and teardrop formation, along with occasional immature WBC precursors.[1213] Bone marrow cells are difficult to aspirate, and biopsy specimens show fibrosis in most patients.[1213] Cytogenetic abnormalities are common in PM if enough marrow cells can be obtained for study.[260,1214] PM is a clonal disease involving all myeloid elements,[1214] and the cause of the associated myelofibrosis is unknown.[1215-1217] However, similar to PV and ET, the *JAK2-V617F* mutation has been found in approximately 50% of patients. Another 10% of patients have been found to have a *W515L* mutation in the thrombopoietin receptor.[1218] Because this disorder is very rare in children, other causes of myelofibrosis need to be ruled out. These causes include nutritional, inflammatory, infectious, and neoplastic disorders.[1219]

The natural history of PM can be variable, with patient survival varying from 1.5 to more than 5 years.[1220] Children with PM may have a more favorable natural history than adults.[1221,1222] Young adults tend to have less severe anemia, higher incidence of splenomegaly, lower frequency of thrombocytosis, and lower frequency of chromosomal abnormalities.[1212] Deletions of the long arm of chromosome 20 or 13—(del(20q) or del(13q)—or a normal karyotype have been associated with more favorable outcomes.[1168] Complications of this disease include bleeding, intercurrent infection, transformation to acute leukemia,[1223] and portal hypertension.[1220] Splenectomy will not cause a further reduction of blood cell counts and therefore should be considered only for mechanical problems, portal hypertension, refractory thrombocytopenia, and hemolytic anemia.[1224] The role of chemotherapy in PM is ill defined, although hydroxyurea, anagrelide, and IFN-α have been used, although none of these approaches is curative.[1225] Given the frequency of *JAK2* mutations in PM, a number of recent adult trials have examined the use of JAK2 or combined JAK1/JAK2 inhibitor in PM with evidence of some bona fide clinical responses, including reduction in splenomegaly and relief from constitutional symptoms, such as fatigue and pruritus.[1226,1227] Ruxolitinib, a combined JAK1/JAK2 inhibitor, was approved by the FDA for high- and intermediate-risk PM in 2011. However, none of these JAK inhibitors selectively targets the *JAK2-V617F* mutation, resulting in side effects such as myelosuppression. Moreover, the effectiveness of these agents in abrogating symptoms in PM appear more related to suppression of JAK-STAT pathway–mediated cytokine-related inflammation characteristic of PM than inhibition of the causative mutant clone.[1178] Thus at this time, allogeneic HSCT remains the only cure and should be considered for higher-risk patients with unfavorable cytogenetics or who are transfusion dependent.[1168]

Mastocytosis

Mastocytosis is a pathologic proliferation and accumulation of mast cells in various tissues in the body.[1228] Mast cells are myeloid cells derived from HSCs but, unlike other lineages, they exit the marrow before they are fully matured and complete their development in the tissues in which they eventually reside.[1229-1231] Given their role in allergic and inflammatory conditions, mast cells are commonly found in vascularized connective tissues such as the skin and the mucosal surfaces of the gastrointestinal tract and respiratory epithelium.[1232] The cutaneous form of mastocytosis is most common in children and may consist of an isolated mastocytoma or diffuse lesions termed *urticaria pigmentosa*.[1233] This is a generally benign condition, although in rare cases progression to systemic mastocytosis (SM) can occur. SM implies mast cell proliferation in an extracutaneous site, most commonly the bone marrow. SM is a clonal myeloproliferative disease frequently associated with a *D816V* point mutation in the gene encoding the KIT tyrosine kinase and presents as varying degrees of mast cell hyperproliferation and impaired differentiation, depending on the subtype.[1228] SM is further divided into subtypes—indolent systemic mastocytosis (ISM), systemic mastocytosis with an associated hematopoietic clonal non–mast cell lineage disease (SM-AHNMD), aggressive systemic mastocytosis (ASM), mast cell leukemia (MCL), mast cell sarcoma, and extracutaneous mastocytoma.[1234] Whereas the *KIT* mutations may be sufficient to result in the indolent form of the systemic disease, additional genetic abnormalities appear to be required for progression to the more aggressive forms of the disease.[1228] For example, the *TET2* mutation found in AML has also been identified in approximately 30% of cases of systemic mastocytosis[1235] and may be associated with more aggressive disease and poor prognosis.[1236] SM may also occur in conjunction with the generally favorable prognostic t(8;21) translocation *(AML1-ETO)* but, in this context, it confers a poor prognosis.[1237,1238] Similarly, MCL is associated with a poor outcome.[1234,1239] MCL occurs predominantly in adults, is frequently aleukemic, and may occur de novo or after localized or systemic mastocytosis, including in childhood.[1234] Patients with MCL may harbor the *KIT-D816V* point mutation, but a number of other novel *KIT* mutations have also been recently identified in these patients.[1234,1240,1241] Treatment strategies include combination therapy with steroids and IFN-α,[1239,1242] cladribine,[1243] and, more recently, tyrosine kinase inhibitors.[1244,1245] Imatinib mesylate, which is known to target the KIT tyrosine kinase in addition to BCR-ABL, has been used in patients with SM. Imatinib has shown preferential efficacy for the minority of patients who lack the *D816V* mutation[1246,1247] and has been approved by the FDA for this indication. Other tyrosine kinase inhibitors, including dasatinib[1248] and masatinib,[1240] have shown modest responses in aggressive mast cell diseases, whereas, more recently, midostaurin (PKC412) has shown some promise with improved responses in imatinib-resistant *D816V*-positive mastocytosis and MCL.[1249,1250]

CONCLUSION

Although considerable progress has been made in improving the remission induction rates in AML, remission is not attained in a significant number of children with newly diagnosed AML. The OS of patients with AML is still not optimal, and the toxicity of treatment is often excessive. Myeloid leukemias, myelodysplastic syndromes, and myeloproliferative disorders are heterogeneous in their molecular pathophysiologic course and are often difficult to treat effectively. With the tremendous improvements in outcome using paradigms of targeted approaches in the treatment of APL with ATRA and As_2O_3, and of CML with imatinib mesylate and other tyrosine kinase inhibitors, interest has grown in applying novel molecularly directed therapies to other types of myeloid disease. While more is understood about the molecular biology of the other types of myeloid malignancies, future studies will incorporate new agents that target malignant cells more specifically while sparing normal hematopoietic stem and progenitor cells. Moreover, recent genomic studies highlighting that the driving mutations in AML are likely few in number in any given patient, together with the evolution of more refined approaches to identify and define leukemic initiating cells, suggest that the ability to rationally apply targeted therapies to eliminate the source of the malignant clone may truly be realized. The incredible advancements in understanding the biology of myeloid diseases, coupled with the development of a large number of novel targeted agents, holds great promise to improve the outcome and reduce the toxicity for increasingly large subsets of patients afflicted by myeloid malignancies.

CHAPTER 52

Infant Leukemias

Rachel Kobos, Neerav Shukla, and **Scott A. Armstrong**

CHAPTER OUTLINE

EPIDEMIOLOGY
PRENATAL ORIGIN OF INFANT LEUKEMIA
RISK FACTORS
BIOLOGY OF MIXED-LINEAGE LEUKEMIA TRANSLOCATIONS
ACUTE LYMPHOBLASTIC LEUKEMIA
- Clinical and Biologic Features
- Prognostic Factors and Outcomes
- Treatment

ACUTE MYELOID LEUKEMIA
- Clinical and Prognostic Features
- Outcomes and Treatment
- Association with Down Syndrome
- Non–Down Syndrome–Associated Infant AMKL

FUTURE DIRECTIONS IN INFANT ACUTE LEUKEMIA TREATMENT
- Targeting Epigenetic Mechanisms
- Immunotherapy
- Modulators of Glucocorticoid Resistance
- FLT3 Inhibitors

The biologic features and clinical characteristics of infant leukemias differ significantly from those of leukemias in older children. Infant leukemias are distinguished not only by the young age of patients at diagnosis but by their unique morphologic, immunologic, clinical, and genetic presentation.[1] For example, acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML) present in infants with a somewhat unique constellation of clinical features, including hyperleukocytosis, massive organomegaly, and central nervous system (CNS) involvement at diagnosis.[2,3] Biologically, the most notable feature distinguishing infant leukemia from leukemia in older children is the high incidence of rearrangements involving the mixed-lineage leukemia (MLL) gene[*] located on chromosome band 11q23.[2,4-7] In the case of infant ALL, unique clinical and biologic characteristics are accompanied by an exceptionally poor prognosis, which is in stark contrast to the cure rates achieved for older children with ALL. In this chapter, the epidemiologic, biologic, and clinical features and the treatment of infant ALL and AML will be discussed.

EPIDEMIOLOGY

The annual incidence of leukemia in the first year of life in the United States is approximately 40 cases per million children.[8] Infants account for 2.5% to 5% of ALL cases and 6% to 14% of AML cases in childhood.[9] Unlike in older children with leukemia, in whom the percentage of ALL cases is approximately four times that of AML, in infants the ratio of ALL to AML is approximately equal. Furthermore, in contrast to an excess of males among older children with leukemia, a slight female predominance is seen in infants with this disease.[8,10,11] Although neuroblastoma represents the most common neoplasm in infants, leukemia is the leading cause of death caused by neoplastic disease in this age group (Table 52-1).[1,8]

PRENATAL ORIGIN OF INFANT LEUKEMIA

The onset of leukemia in infancy strongly suggests a prenatal leukemogenic event, and significant molecular and epidemiologic evidence supports this hypothesis. Molecular studies of monozygotic twins with concordant ALL have demonstrated identical clonal, nonconstitutional rearrangements of the MLL gene and identical oligoclonal, heavy-chain immunoglobulin gene rearrangements in the peripheral blood of these infants.[12-15] This finding suggests the occurrence of a single in utero leukemogenic event in one twin with generation of a clone that is passed to the other fetus by intraplacental metastasis. Further evidence of oncogenesis in utero comes from reports of fetal deaths caused by AML with an MLL gene rearrangement.[16] Moreover, identical MLL gene fusions have been traced back to neonatal Guthrie

---

[*] In this chapter, *KMT2A* will be referred to as MLL. *ALL1* and *HRX* are also alternative names for this gene.

TABLE 52-1 Incidence of Cancer in Infants*

Histology	Incidence (per million)
Neuroblastoma	64.6
Leukemias	40.5
Central nervous system	29.7
Retinoblastoma	26.7
Wilms tumor	22.5
Germ cell	15.3
Soft tissue	15.2
Hepatic	9.5
Lymphomas	4.4
Epithelial	2.8
Other, unspecified	1.2
Bone	0.5

*SEER Program, 1976-1984 and 1986-1994.

genetic screening cards of children who were diagnosed with ALL in their first 2 years of life.[12,17,18] Similarly, leukemia has been diagnosed in fetuses with Down syndrome as early as 33 weeks' gestation, and the characteristic GATA binding protein 1 *(GATA1)* gene mutation associated with megakaryocytic leukemia in young children with Down syndrome has been identified in the neonatal Guthrie genetic screening cards of children in whom leukemia later developed.[19,20]

RISK FACTORS

As with most cancers, the causes of infant leukemia remain largely unknown. However, several epidemiologic risk factors associated with an increased risk of leukemia in young children have been identified. Given the close temporal relationship between embryogenesis and the clinical diagnosis of cancer, most investigations have focused on maternal characteristics and in utero exposures. Maternal alcohol consumption during pregnancy has been correlated with an increased risk of infant AML.[21] Studies have also shown an increased incidence of infant leukemia, particularly ALL, in infants with birth weights higher than 4000 g.[22-24] It has been speculated that high levels of endogenous insulin-like growth factors associated with high birth weight may contribute to leukemogenesis.[9,25] Other proposed risk factors include maternal pesticide and solvent exposure, in utero radiation exposure, and an adverse maternal reproductive history.[26-31] However, given the rarity of infant leukemia, it has been difficult to connect the development of leukemia with any of these exposures or clinical features definitively.

Of particular interest is the potential relationship between maternal consumption of naturally occurring deoxyribonucleic acid (DNA) topoisomerase II inhibitors and the development of infant leukemia. MLL gene rearrangements, similar to those found in many infant leukemias, are common in secondary acute leukemias arising after exposure to DNA topoisomerase II inhibitors, including the epipodophyllotoxins (e.g., etoposide).[32-34] This relationship has led to the hypothesis that transplacental exposure to naturally occurring topoisomerase II inhibitors may be involved in the pathogenesis of infant leukemia.[35] This hypothesis is supported by the finding that both primary infant MLL gene–rearranged leukemias and therapy-related secondary acute leukemias have MLL gene break points that are similarly distributed within the MLL gene break point cluster region (BCR).[33] Furthermore, several dietary bioflavonoids, such as quercetin (found in certain fruits and vegetables) and genistein (found in soybeans) are known topoisomerase II inhibitors and have been shown to induce MLL gene cleavage in vitro.[36] In a study by the Children's Oncology Group (COG), it was found that increased maternal consumption of these and other naturally occurring topoisomerase II inhibitors such as catechins (found in red wine, tea, and cocoa) is associated with an increased risk of MLL gene–rearranged infant AML but not infant ALL.[22,37,38] This association, if true, likely only accounts for a small proportion of infant leukemia cases. Furthermore, the fact that many of these foods are commonly consumed and infant leukemia is rare suggests that this association is either weak or requires a combination of factors. Thus one cannot make recommendations to restrict certain foods to decrease the likelihood of the development of leukemia. Moreover maternal consumption of fruits and vegetables during pregnancy has been associated with a decrease rather than an increase in the risk of infant leukemia overall.[38]

Pharmacogenetic differences in the metabolism of topoisomerase II inhibitors have been hypothesized to modulate the relationship between exposure to these chemicals and the occurrence of MLL gene rearrangements. A common structural feature shared by many topoisomerase II inhibitors, including bioflavonoids, is a quinone moiety. Quinone metabolites generated as by-products of these compounds in the fetal liver have been shown to cleave the MLL gene.[36] Quinones are normally detoxified by reduced nicotinamide adenine dinucleotide phosphatase quinone oxidoreductase (NQO1). The presence of a low-activity variant of NQO1 has been associated with an increased risk of MLL gene–rearranged infant ALL.[39] However, a similar study has also demonstrated a relationship between this NQO1 polymorphism and infant ALL without MLL gene rearrangements.[40]

BIOLOGY OF MIXED-LINEAGE LEUKEMIA TRANSLOCATIONS

The MLL gene located on chromosome band 11q23 is commonly altered in infant leukemia in that it is rearranged in 80% of cases of infant ALL and 60% of cases of infant AML. These chromosomal abnormalities usually

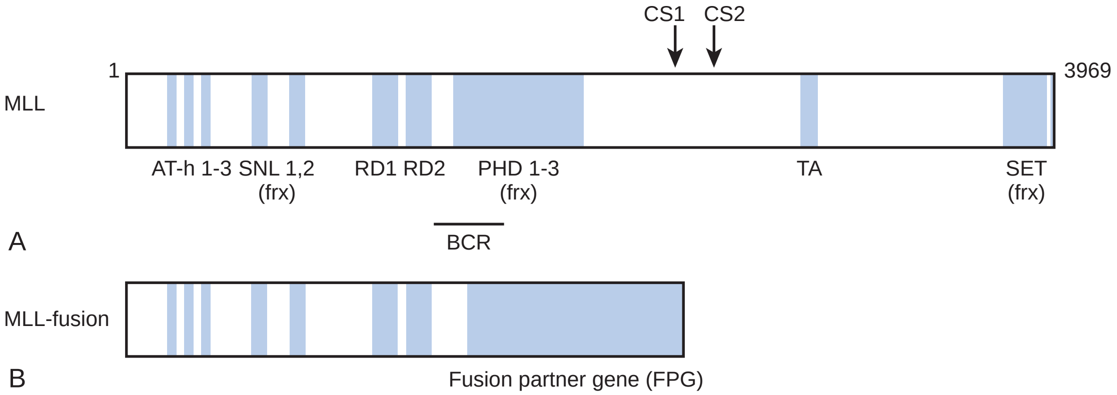

Figure 52-1 Schematic representation of the mixed-lineage leukemia *(MLL)* protein and MLL fusions. **A**, The MLL gene is approximately 89 kb long, consists of 37 exons, and encodes a 3969–amino acid nuclear protein with a complex domain structure (unique domains are highlighted). The N-terminus contains three short AT hook motifs *(AT-h 1-3)*, which are thought to mediate binding to the minor groove of AT-rich genomic deoxyribonucleic acid (DNA) sequences. There are two nuclear localization sites (SNL1 and SNL2) immediately C-terminal to the AT hooks that are followed by a transcriptional repression domain *(RD)* consisting of two functional subunits, RD1 and RD2. RD1 contains a DNA methyltransferase homology domain. The plant homeodomains *(PHD)* zinc finger motifs may mediate binding to a number of different proteins or to chromatin. The transcriptional activation *(TA)* domain recruits the transcriptional coactivator CREB-binding protein and precedes a C-terminal Su(var)3-9, Enhancer of Zeste, Trithorax *(SET)* domain that possesses histone H3 lysine 4 (H3K4) methyltransferase activity. The breakpoint cluster region *(BCR)* spans exons 8 to 13. **B**, Structure of MLL fusion proteins generated by MLL translocations. A typical MLL fusion protein contains the N-terminus of MLL encoded by the first 8 to 13 exons and the C-terminus of one of more than 50 fusion partners. *CS*, Cleavage site.

involve reciprocal translocations, which encode chimeric transcripts that give rise to oncogenic fusion proteins with pronounced transforming potential.[41] A number of groups cloned the MLL-AF4 *(AFF1)* gene in the early 1990s.[42,43,44,45] The MLL-AF4 gene encodes a protein of 2304 amino acids, with the NH2-terminal 1439 amino acids derived from the MLL gene on chromosome 11 and COOH-terminal 865 amino acids derived from the AF4 gene on chromosome 4. Subsequently, close to 100 different translocations have been identified, all of which appear to produce a fusion protein possessing the NH2-terminus of MLL fused in-frame to the COOH-terminus of the fusion partner (Fig. 52-1).[41]

The MLL gene encodes a 3969–amino acid DNA-binding protein that possesses multiple recognizable protein motifs, including an NH2-terminal DNA binding domain, transcriptional activation and repression domains, and a COOH-terminal Su(var)3-9, Enhancer of Zeste, Trithorax (SET) domain that contains histone methyltransferase activity.[46,47] Biochemical studies have identified MLL as a member of a large multiprotein complex that contains members involved in chromatin modification and remodeling. Notably, the complex includes histone deacetylases and members of the switch/sucrose nonfermentable (SWI/SNF) chromatin remodeling complex.[47] Also MLL is recruited to the promoters of select cell cycle regulatory genes by the protein product of the multiple endocrine neoplasia 1 *(MEN1)* tumor suppressor gene, suggesting a role for MLL in tumor suppression and cell cycle control.[48,49] These data support the hypothesis that the MLL protein regulates gene expression via chromatin modification.[50]

Analysis of Mll knockout mice has suggested that Mll plays an important role in development and hematopoiesis through maintenance of appropriate homeotic (Hox) gene expression.[51,52] Detailed studies assessing the specific role of Mll in hematopoietic development have shown that Mll is necessary for definitive hematopoiesis and for the expansion of hematopoietic progenitors and stem cells found in the aorta-gonad-mesonephros region of the developing embryo.[53] The defect in hematopoietic progenitor expansion can be rescued by reexpression of Hox genes, confirming the importance of Mll-mediated Hox gene expression during hematopoiesis.

Multiple studies have demonstrated the ability of Hox genes to induce leukemia in mice,[54] and the t(7;11)(p15;p15) translocation found in some human acute myeloid leukemias results in a fusion of the homeobox A9 *(HOXA9)* gene to the nucleoporin 98kDa *(NUP98)*.[55,56] Given the apparent importance of HOX genes in leukemogenesis, it seems likely that translocations involving MLL, a known regulator of HOX genes, alters expression of HOX genes that are important for leukemogenesis. Further support for HOX genes as central regulators of MLL gene–induced leukemogenesis comes from gene expression studies that have found multiple HOXA cluster genes more highly expressed in MLL gene–rearranged myelogenous and lymphoblastic leukemias compared with MLL gene germline leukemias.[57,58,59,60]

Gene expression studies of human MLL gene–rearranged B-precursor ALL have demonstrated that hundreds of genes are differentially expressed when compared with other B-precursor ALLs.[57-59,61] Based on the magnitude of the differences in gene expression, it appears that MLL gene translocations specify a unique lymphoblastic leukemia. Other large gene expression studies have also shown that ALLs with distinct chromosomal rearrangements have unique gene expression profiles, providing support for this hypothesis.[59] The genes that are relatively highly expressed in MLL gene–rearranged B-precursor ALL are those associated with hematopoietic progenitors and developing myeloid cells, whereas the genes expressed at lower levels are genes associated with lymphoid identity. Studies have also defined specific gene expression signatures associated with MLL gene translocations in pediatric—and in some cases infant—AML blasts.[60] It is of interest that even though clear differences exist in expression of lineage-associated genes between MLL gene–rearranged ALL and MLL gene–rearranged AML, a core gene expression profile appears to be found in all MLL gene–rearranged human leukemias, independent of the lineage markers.[60] Presumably, MLL fusion proteins directly regulate a subset of these genes. This theory is further supported by the fact that this MLL-associated signature consists of multiple highly expressed HOX genes.

The observation that leukemic cells bearing an MLL gene translocation often coexpress both myeloid and lymphoid markers raises the possibility that MLL fusion genes selectively transform hematopoietic stem cells (HSCs). If so, this HSC population would have an inherent self-renewal capacity that could be co-opted for leukemogenesis. Xenograft transplantation studies have demonstrated that a rare subpopulation of CD34+ and CD38− human myeloid leukemia cells are able to transfer the disease to immunodeficient mice, providing support for HSCs as the normal compartment from which leukemia-initiating cells (leukemia stem cells) might arise.[62] Alternatively, the translocation event between the MLL gene and a partner gene may affect a more committed population. In this scenario, the MLL fusion protein might confer a self-renewal and proliferative capacity to these short-lived progenitors and allow them to initiate leukemogenesis. Studies have suggested that Mll fusion proteins and potentially other translocation-associated fusion proteins are capable of inducing leukemia when expressed in fully committed myeloid progenitors, such as granulocyte-macrophage progenitors.[63,64] These findings are of particular importance because they suggest that products of chromosomal translocations found in human leukemias are able to induce a program of self-renewal that is not normally present in hematopoietic progenitors.

Multiple lines of evidence now point to a multistep pathogenesis of human acute leukemia. Elegant epidemiologic studies have suggested that childhood leukemias require at least two and probably more genetic events to occur for the development of leukemia. In particular, lymphoblastic leukemias with *ETV6-RUNX1 (TEL-AML1)* rearrangements appear to develop after a multistep process. TEL-AML1 rearrangements have been detected in blood taken at birth from a child in whom ALL then developed 3 to 5 years later. This finding suggests that TEL-AML1 rearrangements are the first genetic event but that other mutations also are required for the development of ALL.[65] Similar studies have been performed on blood spots from children in whom MLL gene–rearranged ALL subsequently developed, and the MLL gene translocations clearly develop in utero, even though the leukemias become apparent at some point during the first year of life.[12]

Receptor tyrosine kinases are attractive candidates as signaling molecules that may cooperate with translocation-associated fusion proteins during leukemogenesis. Ever-increasing evidence has suggested that activated kinases play a central role in the pathogenesis of leukemias and myeloproliferative syndromes.[66] The most dramatic evidence for such a role is activation of the Abelson (ABL) tyrosine kinase by the BCR-ABL fusion produced by t(9;22) and its inhibition by imatinib (Gleevec).[67,68] Other mutant kinases frequently identified in AML and subsets of ALL are the receptor tyrosine kinases fms-related tyrosine kinase–3 (FLT3), c-KIT, and platelet-derived growth factor receptor, among others.[66] Given the high level expression and recurrent mutation of FLT3 in MLL gene–rearranged ALL, studies are under way to assess FLT3 inhibitors in patients with MLL gene–rearranged ALL (discussed later). As approaches to target the rat sarcoma (RAS) signaling pathway are further developed, RAS inhibitors might also be considered in RAS-mutant cases.

Given the central importance of the MLL fusion protein generated by the MLL gene translocation, significant effort has been directed toward defining a unifying mechanism of oncogenesis, because it would facilitate pharmacologic targeting of shared leukemogenic mechanisms. Some broad patterns have emerged that have focused on mechanisms that control MLL target gene expression. The most commonly occurring MLL gene translocations generate chimeric fusion proteins that harbor the NH3-terminus of MLL fused to proteins that are normally part of nuclear complexes, the function for which is now emerging.[69] Nuclear proteins such as AF4, AF9, ENL, ELL, AF10, AF17, and AFF4—fusions of which together account for the vast majority of MLL leukemias—normally directly or indirectly associate with complexes that regulate gene expression.[70-75] A number of complexes linked to transcriptional elongation have been reported, often with overlapping protein components, such as the ENL-associated protein (EAP) complex,[72] the AF4/ENL/P-TEFb (AEP) complex,[75] the super elongation complex (SEC),[74] and the complex comprising the disruptor of telomeric silencing (DOT1)–like histone 3 lysine 79 (H3K79) methyltransferase (DOT1L; DOT1L containing complex [DotCom]; Fig. 52-1).[73] These data point to aberrant control of transcriptional elongation as critical for MLL fusion–mediated oncogenesis.

The histone methyltransferase DOT1 is a non-SET domain containing histone methyltransferase solely responsible for catalyzing the methylation of H3K79.[76] H3K79 methylation is associated with most genes that are highly expressed in hematopoietic cells and is believed to be involved either in activation or maintenance of gene expression. Thus a prominent hypothesis is that MLL fusion proteins induce aberrant gene expression via recruitment of DOT1L (among other protein complexes) to MLL target genes, including the HOXA cluster genes. Genome-wide studies have demonstrated elevated H3K79 methylation at MLL target genes in MLL gene–rearranged ALL and AML cells.[77-79] Several recent studies using conditional loss of function mouse models and ribonucleic acid (RNA) interference approaches have formally demonstrated a critical role for DOT1L in MLL fusion–driven leukemias.[79-82] These studies demonstrate that genetic inactivation of DOT1 leads to a decrease in MLL fusion target gene expression, including a rapid decrease in HOXA cluster gene expression that is correlated with an antiproliferative response. Remarkably, inactivation of DOT1L does not affect the transformation potential of a number of other leukemogenic oncogenes. Furthermore, microarray-based gene expression studies showed that MLL-fusion target gene expression is much more dependent on DOT1L than is gene expression broadly.[79] These studies highlight the importance of aberrant H3K79 methylation for the transforming activity of MLL fusion proteins including MLL-AF4, MLL-AF9, MLL-AF10, and MLL-ENL and show that DOT1L is required for continued HOXA cluster gene expression. These results potentially have profound clinical implications because these fusions comprise the vast majority of MLL gene–rearranged leukemias; small-molecule DOT1L inhibitors have been developed and are entering clinical trials (discussed later).

ACUTE LYMPHOBLASTIC LEUKEMIA

Clinical and Biologic Features

ALL in infants is characterized by a high leukocyte count at presentation, marked hepatosplenomegaly, and a relatively high incidence of CNS involvement.[2,3,83,84] The immunophenotype of infant ALL is usually that of an immature B-lineage precursor and is characterized by a lack of cluster of differentiation (CD)–10 expression, as well as by the coexpression of myeloid-associated antigens, such as CD14, CD15, and CDw65. Lack of CD10 expression and coexpression of myeloid markers correlates with the presence of an MLL gene rearrangement, which is present in 80% of infants who have ALL compared with only 2% to 4% of older children who have ALL.[4,6,85-87] MLL gene rearrangements are more frequent in younger infants, with approximately 90% of infants younger than 6 months at diagnosis having MLL gene rearrangements in their leukemic blasts compared with 30% to 60% of infants aged 6 to 12 months.[4,88,89] The most common MLL gene translocation observed in infant ALL is t(4;11)(q21;q23), resulting in the MLL-AF4 fusion. This translocation is found in approximately 70% of MLL gene–rearranged infant ALL cases. Other common translocations include t(11;19), resulting in the MLL-ENL fusion, and t(9;11), resulting in the MLL-AF9 fusion, which occur in 15% and 4% of MLL gene–rearranged infant ALL cases, respectively.[6,85-87,90] Cases of infant ALL without an MLL gene rearrangement generally resemble the more common B-precursor ALL phenotype (CD19+, CD10+) typical of older children with ALL. Chromosomal abnormalities known to be favorable in older children with ALL, such as high hyperdiploidy (51 to 65 chromosomes, or a DNA index more than 1.16) and the *TEL-AML1* fusion gene, are notably absent in infants.[84] The distinguishing presenting characteristics of infants with ALL are summarized in Table 52-2.

*B-lineage patients only.

A striking feature of MLL gene–rearranged infant ALL is the paucity of secondary genomic alterations compared with older children who have pre–B-ALL.[91-94] A mutational profiling study of oncogenic RAS alterations in MLL gene–rearranged ALL samples identified mutations in 15 of 109 samples (14%). Of the 38 samples with a t(4;11) MLL gene rearrangement, 9 (24%) were found to have RAS mutations. Identification of a RAS mutation was found to be an independent poor prognostic risk factor.[95]

Prognostic Factors and Outcomes

Despite extraordinary improvements in the cure rates for older children with ALL, the prognosis for infants with this disease remains poor. Historically, infants with ALL who were treated with standard regimens had a less than 20% event-free survival (EFS). During the past decade, intensified regimens designed especially for infants have resulted in improved rates of EFS ranging from 28% to 54% (Table 52-3).[84,85,87,89,97-104] In contrast, EFS rates are greater than 80% for older children with ALL.[105-108] Although 90% to 95% of infants with ALL achieve remission after initial induction chemotherapy, a favorable outcome is hampered by an exceedingly high relapse rate, typically within the first year after diagnosis.

Several closely related adverse prognostic factors have been identified for infants with ALL, including the presence of an MLL gene rearrangement, lack of CD10 expression, coexpression of myeloid markers, age less than 6 months at diagnosis, high white blood cell (WBC) count at presentation, CNS involvement, and poor early response to prednisone therapy.[87,97,109,111] In multivariate analyses, the presence of an MLL gene rearrangement, age younger than 6 months, and a poor early response to prednisone therapy consistently emerge as the most important adverse prognostic features.[89,102] In many studies, the presence of an MLL gene rearrangement is the most important independent predictor of outcome for infants.[88] Long-term EFS for infants with MLL gene–rearranged ALL has ranged from 13% to

34%, versus 52% to 95% for infants with germline MLL (Fig. 52-2).[4,6,87-89,97,99,102,112]

In addition to MLL gene status and age, early response to therapy has been shown to be an important predictor of outcome in infants with ALL. The Berlin-Frankfurt-Munster group has identified a poor response to prednisone as one of the strongest predictors of outcome for infants with ALL, regardless of MLL gene status.[97] Infants with ALL who have a poor response to a 7-day prednisone monotherapy prophase (defined as more than 1000 blasts/μL present in peripheral blood on day 8) had a 6-year EFS of only 15%, compared with a 6-year EFS of 53% for infants with a good response to prednisone. This finding was reproduced in the most recent clinical trial

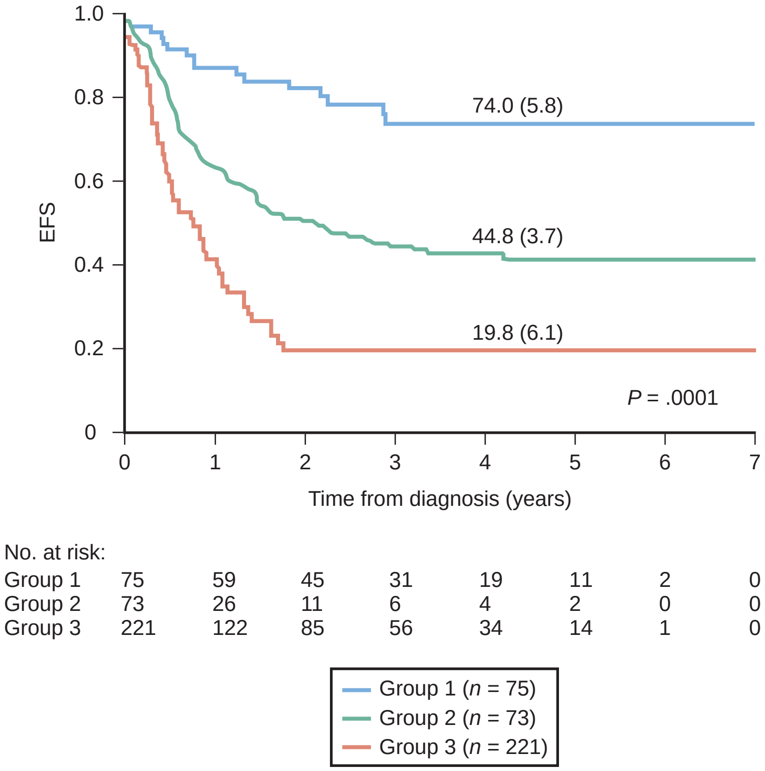

Figure 52-2 Event-free survival *(EFS)* for infants with acute lymphoblastic leukemia who were treated in the Interfant 99 trial.[103] Group 1 consisted of patients with the germline mixed-lineage leukemia (MLL) gene. Group 2 consisted of patients with an MLL gene rearrangement, age younger than 6 months at diagnosis, and white blood cell count higher than 300×10^9 cells/L at diagnosis. Group 3 consisted of all other patients. *(Modified from Pieters R, Schrappe M, De Lorenzo P, et al: A treatment protocol for infants younger than 1 year with acute lymphoblastic leukemia [Interfant-99]: an observational study and a multicentre randomized trial.* Lancet *370:240–250, 2007.)*

conducted by the Interfant study group (Interfant 99), in which infants with a poor response to steroids had a 30% 4-year EFS, compared with a 56% 4-year EFS for good responders.[89] Similarly, the Children's Cancer Group found a threefold excess risk of treatment failure in infants whose bone marrows contained more than 5% leukemic blast cells after 14 days of multiagent chemotherapy.[102]

It has been suggested that the specific MLL gene fusion partner might also have prognostic significance for infants with ALL.[102,109] However, in a large retrospective study that included data from more than 200 cases of MLL gene–rearranged ALL in infants, no significant difference in outcome was found among cytogenetic subgroups, including t(4;11), t(9;11), t(11;19), and other 11q23 rearrangements.[90] The Interfant study group also failed to find any association between the specific MLL gene translocations and treatment outcome.[89] More recently, localization of the fusion break point has been identified as a potential prognostic biomarker, with break points within MLL intron 11 demonstrating poorer outcomes.[113] Gene expression profiling has also identified candidate prognostic markers. Analysis of 97 samples from P9407, a COG trial for infant ALL conducted between 1996 and 2006, identified patients with low FLT3 expression as having superior outcomes, which had previously been observed in patients enrolled in the Interfant 99 trial.[114] Patients with high FLT3 expression, in addition to either high iroquois homeobox 2 (IRX2) or high transforming, acidic coiled-coil containing protein 2 (TACC2) expression, had very poor 4-year EFS rates.[110]

Treatment

Attempts to improve clinical outcomes for infants with ALL have generally involved intensifying treatment regimens and incorporating chemotherapeutic agents more commonly used in AML therapy. An ongoing international trial, Interfant 06, is evaluating the outcome of patients randomly treated with either a standard consolidation approach using mercaptopurine, cyclophosphamide, and cytarabine or two consecutive AML-based cycles that include cytarabine, etoposide, and both daunorubicin and mitoxantrone. Several preclinical and clinical findings have also informed the development of treatment regimens for infants with ALL, including clinical response to prednisone therapy and in vitro drug sensitivity profiles of infant ALL lymphoblasts. When compared with cells from older children with ALL, leukemic blasts from patients with infant ALL are more often resistant to glucocorticoids (prednisone and dexamethasone) and L-asparaginase in in vitro assays. Importantly, both of these agents are central components of current ALL therapeutic regimens.[97,115-117] In vitro studies of sarcoma (Src) kinase inhibition demonstrated sensitization of MLL gene–rearranged ALL cell lines to glucocorticoids, highlighting this strategy as a possible future therapeutic option in these patients.[118,119] Given the prognostic significance of prednisone response in ALL, some infant ALL treatment groups now risk-stratify infants on the basis of prednisone response and other common prognostic factors, including MLL gene status, age, and diagnostic WBC count.[89]

Although infant ALL blasts are relatively resistant to some common ALL therapeutic agents, they are remarkably sensitive to cytosine arabinoside (ara-C; cytarabine), a drug commonly used in the treatment of AML.[115,116] This increased sensitivity may be related in part to elevated expression of the human equilibrative nucleoside transporter–1, which allows cytarabine to permeate the cell membrane at low to moderate concentrations.[120-123] Clinical data are accumulating to suggest that increased use of cytarabine may benefit infants with ALL.[89,99,102] Investigators from the Dana-Farber Cancer Institute ALL Consortium first reported an improved outcome in a small number of infants treated with intensified therapy that included high-dose cytarabine.[124] Subsequently the cooperative groups COG and Interfant incorporated high-dose cytarabine into their intensified therapeutic regimens, a strategy that is likely to have contributed to the improvements in EFS for infants with ALL observed during the past decade.

Hematopoietic Stem Cell Transplantation

The role of hematopoietic stem cell transplantation (HSCT) in first remission for infants with ALL is controversial. Small uncontrolled studies have suggested that HSCT may benefit infants with MLL gene rearrangements.[125-127] Although encouraging, these results must be interpreted with caution, given the small sample sizes, the failure to control for waiting time from diagnosis to transplantation, and the use of total body irradiation in cytoreduction, which many groups are avoiding given the significant morbidity associated with radiation in this age group.[128] The most recent Interfant study group trial (Interfant 99) identified a subgroup of high-risk patients who may benefit from HSCT, including those diagnosed before 6 months of age and who have either a poor steroid response or a high WBC count at diagnosis.[129] In contrast, a larger retrospective analysis did not confirm a benefit of HCST for infants with ALL.[90] Similarly, the COG found no benefit of transplantation compared with intensive chemotherapy alone.[87] Further studies are needed to adequately define the role for stem cell transplantation in infants with ALL.

Toxicity and CNS-Directed Therapy

A major consideration in the treatment of ALL in infants is the significant potential for short- and long-term toxicity, given the intensity of treatment regimens and the lack of pharmacokinetic and pharmacodynamic studies to ensure optimal dosing of chemotherapeutic agents in infants. Of particular concern is the risk of debilitating neuropsychological sequelae, especially in infants receiving cranial radiation. Severe neurologic deficits and learning disabilities have been reported in long-term survivors of infant ALL who received cranial radiation.[3,98,99] In almost all subsequent clinical trials, attempts have been made to reduce neuropsychological complications by minimizing, delaying, or eliminating cranial radiation. Currently most investigators favor eliminating radiation in infants with ALL, even those with CNS leukemia at diagnosis, relying instead on intensive systemic and intrathecal chemotherapy. Several observations have supported this approach, including outcomes from large cooperative group studies documenting very low CNS relapse rates (3% to 9%) with intensive systemic and intrathecal chemotherapy alone.[89,100,102]

ACUTE MYELOID LEUKEMIA

Clinical and Prognostic Features

Infant AML is characterized by a high incidence of myelomonoblastic (French-American-British [FAB] M4) or monoblastic (FAB M5) morphologic features, frequent CNS involvement, extramedullary disease (including skin involvement), and relatively high leukocyte counts at diagnosis.[2]

MLL gene rearrangements are found in about 60% of infant AML cases, with the most common translocation being t(9;11), resulting in the MLL-AF9 fusion, followed by t(11;19), resulting in the MLL-ENL fusion. MLL gene rearrangements in infant AML are associated with a FAB M4 or M5 morphology and hyperleukocytosis.[111,130,131] Other cytogenetic abnormalities in infant AML of the FAB M4 or M5 morphologic subtype include inv(16) and monosomy 7. Translocations commonly seen in older children with AML, such as t(8;21) and t(15;17), are rare in infants with AML.[132]

Unlike in infant ALL, the prognostic factors that predict outcome for infant AML are not clearly defined. Several studies have identified a variety of potential prognostic factors for infants with AML, including presenting WBC count, FAB M4 or M5 morphology, gender, and the presence of an MLL gene rearrangement, but the findings of these studies have varied widely and are often contradictory.[133-138] The difficulty in clearly identifying consistent prognostic factors in infant AML may point to more biologic heterogeneity in infant AML (compared with infant ALL), as well as significant variations in the definition of study groups and treatment regimens.

The prognostic significance of MLL gene rearrangements in infant AML is unclear. Several studies have found that MLL gene rearrangements lack prognostic significance in childhood AML, whereas at least one study has found a trend toward a worse outcome.[131,133,139-142] Alternatively, several groups have demonstrated that the presence of a specific translocation, t(9;11)(p22;q22) or MLL-AF9, confers a favorable prognosis.[138,143-146] For example, the investigators at St. Jude Children's Research Hospital found the presence of t(9;11) to be an important prognostic factor for patients treated in four consecutive pediatric AML trials. The 5-year EFS for infants whose leukemia cells carried t(9;11) was 70% versus 25% for those with other cytogenetic abnormalities, including other MLL gene rearrangements.[147]

The Berlin-Frankfurt-Munster Group recently reported on the clinical characteristics of 62 pediatric patients with AML who had t(8;16)(p11;p13) translocations. The average age of diagnosis was very young (1.2 years), with common features of erythrophagocytosis (70%), leukemia cutis (58%), and disseminated intravascular coagulation (39%). Strikingly, seven patients diagnosed within the first month of life underwent spontaneous remission of their disease, three of whom remained in remission at the time of publication.[148]

Outcomes and Treatment

Whereas age-associated treatment results are clearly evident in childhood ALL, with infants faring significantly worse, similar age-related differences in outcomes have not been routinely observed in AML. In large clinical trials in children with AML, EFS rates of 22% to 73% have been reported for infants, which do not differ significantly from outcomes achieved in older children (Table 52-4).[126,147,149-156] Given that treatment outcomes do not differ by age group, there has been no compelling clinical justification for the development of unique treatment strategies for infants with AML. Current therapeutic regimens for infants and older children focus on intensive remission induction and consolidation chemotherapy, with HSCT reserved for patients with matched sibling donors and those who have poor prognostic features. Although treatment regimens for infants with AML do not currently differ from those for older children, some potential differences have been proposed. The observation that t(9;11) may be a favorable prognostic factor in infants with AML has resulted in controversy with regard to whether bone marrow transplantation in first remission should be considered in this subgroup of patients. Another possible exception includes infants with megakaryoblastic leukemia who are harboring t(1;22)(p13;q13); these infants appear to have a particularly poor prognosis and may be candidates for more aggressive treatment or innovative experimental therapy.[157,158]

Association with Down Syndrome

Several genetic syndromes including monosomy 7, del (7q) syndromes, Noonan syndrome, and neurofibromatosis type 1 are associated with an increased risk of developing myelodysplasia, myeloproliferative diseases, and myeloid leukemia in infancy. A striking example is the increased incidence of leukemia seen in children with Down syndrome. Persons with Down syndrome have a tenfold to twentyfold increased lifetime risk of developing leukemia, including ALL and AML. The most marked increase is observed in young children with Down syndrome in whom acute megakaryoblastic leukemia (AMKL; FAB M7) develops.[159] The risk of AMKL is estimated to be 500 times higher in children with Down syndrome than in the general population. A transient form of megakaryoblastic leukemia, known as transient leukemia, transient abnormal myelopoiesis, or transient myeloproliferative disorder (TMD), often precedes AMKL in newborn infants with Down syndrome (or trisomy 21 mosaicism). Although the true incidence of TMD is unknown, a small study has found that 10% of neonates with Down syndrome have evidence of TMD on examination of their peripheral blood smears.[160] The true incidence of TMD is likely to be higher, given that fetuses who develop TMD in utero may not be identified and neonates with subtle manifestations of TMD may go unnoticed.[161,162]

Clinically the presentation of TMD can be variable, ranging from asymptomatic, with an incidental finding of an elevated WBC count and circulating blasts in the peripheral blood, to fulminating life-threatening disease, with severe liver dysfunction and liver fibrosis, multiple effusions, and respiratory compromise. TMD has also been associated with intrauterine death and hydrops fetalis.[162,163] TMD usually has a relatively benign course, with spontaneous remission within the first 3 months of life. However, in 13% to 33% of infants who recover from TMD, AMKL will go on to develop by age 3 years.[164-166] Often the subsequent leukemia is preceded by a myelodysplastic phase, with progressive cytopenias and increasing marrow fibrosis. In a prospective study of neonates with TMD conducted by the COG, it has been found that 64% of infants with TMD experienced a spontaneous and continuous remission, 17% had an early death (predominantly because of liver failure), and 19% experienced a spontaneous remission but went on to develop AMKL at a mean age of 20 months.[166]

TMD and AMKL in persons with Down syndrome nicely illustrate the multistep process of leukemic transformation. Biologically, the blasts from TMD and AMKL are morphologically and immunophenotypically similar and consistent with megakaryoblastic progenitors.[167-169] Chromosomal abnormalities are more frequent in AMKL than in TMD, with the most common abnormality being trisomy 8.[160,170] The leukemic blasts of TMD and AMKL in patients with Down syndrome have been shown to harbor a unique mutation of the gene encoding the hematopoietic transcription factor *GATA1*.[171,172] These mutations are found exclusively in Down syndrome–associated TMD and AMKL and have not been found in non–Down syndrome–associated AMKL or in patients with Down syndrome who have ALL.[171,173,174] *GATA1* has essential functions during normal erythroid and megakaryocytic development.[175,176] Most *GATA1* mutations cluster within exon 2 and result in the expression of a truncated mutant protein, GATA1s, which retains its DNA binding zinc fingers but lacks the amino-terminal transcriptional activation domain. Studies in model systems have suggested that GATA1 possesses unique activity that leads to expansion of an early megakaryocyte progenitor in the fetal liver, perhaps explaining why *GATA1* mutations are only found in infant AMKL from patients with Down syndrome.[177] Several recent studies have demonstrated that although TMD is caused by constitutional trisomy 21 and *GATA1* mutations, progression to AMKL is caused by the acquisition of additional mutations. These mutations have been identified in multiple cohesin components and epigenetic regulators, as well as wingless type (WNT), Janus kinase–signal transducer and activator of transcription (JAK-STAT), and mitogen-activated protein kinase/phosphatidylinositol 3′-kinase (MAPK/PI3K) pathway genes.[178-180]

Another remarkable characteristic of AMKL in Down syndrome is its extraordinary responsiveness to AML therapy.[135,181-184] In early clinical trials, the outcomes for patients with AML and Down syndrome were not favorable, although poor outcomes were primarily the result of treatment-related toxicity rather than relapsed or refractory disease. Subsequently, patients with Down syndrome and AML who were treated in a series of large multicenter pediatric trials were found to have a better response to chemotherapy and better survival rates than were patients without Down syndrome. EFS rates for children with Down syndrome and AML treated by modern protocols range from 80% to 100%.[135,181,182,184-187] Current treatment protocols for patients with Down syndrome and AML favor less intensive regimens, which aim to maintain high cure rates while minimizing toxicity.

Non–Down Syndrome–Associated Infant AMKL

AMKL also occurs in a subset of infants who do not have Down syndrome. AMKL in these infants frequently harbors the t(1;22)(p13;q13) translocation.[157,158,188] The t(1;22)(p13;q13) translocation is found almost exclusively in infants and young children with AMKL. This disorder is typically accompanied by significant bone marrow fibrosis and organomegaly and has a poor prognosis, with a median survival of only 8 months. The t(1;22)(p13;q13) characteristic of this malignancy is associated with the fusion of RNA-binding motif protein–15 (*RBM15*), an RNA recognition motif-encoding gene, and megakaryoblastic leukemia–1 (*MKL1*), a gene encoding an SAP (scaffold attachment factor A and B [SAF-A/B], Acinus, and protein inhibitor of activated STAT [PIAS]) DNA binding domain.[189] The mechanism by which this fusion contributes to leukemogenesis is not yet fully understood, although it has been shown that Rbm15-Mkl1 can alter SET domain containing 1b (Setd1b) histone methyltransferase activity, leading to epigenetic dysregulation.[190] Alternate translocations have also been identified in non–Down syndrome AMKL. A recent genomic study of non–Down syndrome AML identified a novel cryptic translocation of chromosome 16 involving core-binding factor, runt domain, alpha subunit 2, translocated to 3 *(CBFA2T3)*, a member of the eight-twenty-one (ETO) family of nuclear corepressors, and *GLIS2*, a GLI family transcription factor. This translocation was identified in 27% of studied cases and was associated with significantly poorer outcomes.[191] Translocations joining *NUP98* on chromosome 11 to *KDM5A (JARID1A)* on chromosome 12 are found in approximately 10% of AMKL cases and are characterized by HOXA/B gene overexpression. Unique clinical or prognostic characteristics have not been identified in this subset of patients.[192]

FUTURE DIRECTIONS IN INFANT ACUTE LEUKEMIA TREATMENT

Although morphologic complete remission is achieved in the vast majority of infants with ALL, a favorable outcome is hampered by an exceedingly high relapse rate in the first year after diagnosis. To date, intensification of conventional chemotherapeutic agents has resulted in only incremental improvement in the prognosis of infants with ALL, emphasizing the need for novel, more effective therapies.[193]

Targeting Epigenetic Mechanisms

In the past few years we have seen an explosion in the understanding of the normal function of the MLL protein and the fusion proteins generated by MLL translocations. We now know that the wild-type MLL protein is a histone methyltransferase that influences the expression of important developmental genes such as the HOX genes. Indeed, these proteins that influence gene expression via modification of histones or other components of chromatin (known as epigenetic regulators) appear to be central to the development of a number of different leukemia subtypes and perhaps other cancers. Given that enzymes control many of the epigenetic processes, the possibility that a new generation of therapies that targets epigenetic regulators may be on the horizon is generating tremendous excitement. Histone deacetylase inhibitors and DNA hypomethylating agents may work through the modulation of either DNA or histone modifications, and such approaches are being considered in pediatric leukemias, including infant MLL gene–rearranged leukemias. Although a specific rationale does not exist as to why MLL gene–rearranged leukemias should be more sensitive to these approaches than other leukemias, it is worth considering these agents for clinical trials.

However, new data provide a potential rational approach to target MLL fusion proteins generated by MLL translocation. Recent studies have shown that leukemic transformation by MLL fusion proteins is highly, and somewhat uniquely, dependent upon the histone methyltransferase DOT1L that methylates histone H3 on lysine 79.[77-79] Remarkably, it appears that this enzyme is required for continued proliferation of most if not all MLL gene–rearranged leukemias, and thus a therapeutic agent targeting DOT1L might benefit patients with leukemia who are bearing any MLL translocation.[194] Preclinical studies using specific small molecule DOT1L inhibitors have been completed and demonstrate remarkable activity and minimal toxicity in animal models.[195,196] The phase I trials for such approaches are under way in adults with relapsed/refractory leukemia. The possibilities that this approach may represent are generating tremendous excitement. However, it will be important to thoroughly assess the toxicity of such approaches in adults and children given that this approach to cancer therapy is completely new.

Immunotherapy

Novel therapies directed at proteins on leukemic cells may offer further promise in treating infant leukemia. Three approaches to targeting CD19 for the treatment of pre–B-ALL exist. Blinatumomab is a bispecific antibody that binds both CD19 and CD3, thereby engaging T cells to attack leukemia cells. In a phase II trial of adult patients with persistent minimal residual disease (MRD), 80% of subjects achieved negative MRD after treatment with blinatumomab, and responses in children have already been reported.[197,198] The pediatric phase II trial is under way. Positive results using autologous chimeric antigen cells directed against CD19 have now been reported in both pediatric and adult patients, and further studies in patients with infant ALL will need to be pursued.[199,200] Finally, a novel antibody-drug conjugate, SGN-CD19a, which combines an anti-CD19 monoclonal antibody with an inhibitor of tubulin polymerization (monomethyl auristatin F), is being evaluated in patients with pre–B-ALL and may prove to be effective for treatment of infant ALL. All three therapies target the CD19 protein, which may be a limitation in MLL gene–rearranged infant ALL, given the existence of CD19-negative subpopulations in this leukemia.[201]

Relative to ALL, current options for immunotherapy in AML are fewer. SGN-CD33a, an antibody-drug conjugate in development, targets CD33 and utilizes a pyrrolobenzodiazepine dimer to create DNA damage. This drug is only recently entering into clinical trials but may be worth pursuing in future trials that assess novel infant AML therapy.[202]

Modulators of Glucocorticoid Resistance

Cellular drug resistance may significantly contribute to the poor prognosis of infant ALL.[193] Infants with ALL are more likely to have a poor in vivo response to prednisone than are older children with ALL.[97,117] In addition, leukemic blasts from infants with ALL are highly resistant to glucocorticoids in vitro.[115,116] Both in vivo and in vitro responses to prednisone are highly predictive of clinical outcome in childhood ALL, and thus the mechanisms of glucocorticoid resistance are attractive targets for novel therapeutic agents.[203,204] Gene expression profiling of steroid-resistant and steroid-sensitive lymphoblasts indicates that myeloid cell leukemia–1 (MCL1), an antiapoptotic member of the B-cell lymphoma–2 (BCL2) family, may be an important modulator of glucocorticoid resistance in ALL.[205,206] Furthermore, a gene expression–based chemical genomics screen has identified sirolimus (more commonly known as rapamycin), the mammalian target of rapamycin (mTOR) inhibitor, as an agent capable of reversing a gene expression signature associated with glucocorticoid resistance. It has also been shown that sirolimus sensitizes lymphoid cells to glucocorticoids via the modulation of MCL1 levels.[205] Other modulators of MCL1 have been identified, including honokiol, a naturally occurring compound, and the synthetic inhibitors Seliciclib (CYC202, or R-roscovitine) and R-etodolac (SDX-101).[207-210] The potential to overcome glucocorticoid resistance in infant ALL by compounds that modulate MCL1, or other antiapoptotic molecules such as BCL2, makes agents targeting the apoptotic pathway attractive candidates for further investigation as therapeutic approaches for the treatment of infant ALL.[211]

FLT3 Inhibitors

Lymphoblastic leukemias with rearrangements of the MLL gene display a unique gene expression profile that distinguishes them from other subgroups of ALL and AML.[57,59-61] This distinct gene expression profile has led to the identification of several potential therapeutic targets. One of the most highly expressed genes distinguishing MLL gene–rearranged ALL from other acute leukemias is *FLT3*, the gene encoding fms-like tyrosine kinase 3.[57,212] Activating *FLT3* mutations through internal tandem duplication (ITD) of the juxta-membrane domain (FLT3/ITD) occur in 11% to 17% of de novo pediatric AML cases and are associated with significantly poorer outcomes.[213-216] After identification of these activating mutations, numerous small-molecule FLT3 inhibitors were developed, and clinical trials are under way to evaluate the effectiveness of these compounds in the treatment of AML.[217-222] However, FLT3/ITD–positive AML is rare in infant AML, accounting for fewer than 2% of cases, and therefore may have very limited benefit in this population.[216] High levels of *FLT3* expression have also been demonstrated in MLL gene–rearranged ALL. FLT3 inhibitors have been shown to be active against MLL gene–rearranged cell lines that overexpress *FLT3*, as well as in primary MLL gene–rearranged lymphoblasts.[223-225] Additionally, results from in vitro experiments with MLL gene–rearranged cell lines have suggested that FLT3 inhibitors may work synergistically with several standard chemotherapeutic agents, including ara-C.[225,226] However, the sequence of administration of these agents appears to be important. In vitro studies have found that to achieve maximal synergistic cytotoxicity, the chemotherapeutic agent must be given immediately prior to the FLT3 inhibitor, whereas pretreatment with the FLT3 inhibitor followed by the chemotherapeutic agent results in antagonistic effects.[226,227] Furthermore, disruption of the stromal microenvironment through CXCR4 inhibition leads to increased sensitivity of MLL gene–rearranged ALL xenograft models to FLT3 inhibition.[228] The preclinical data demonstrating activity of FLT-3 inhibitors in infant ALL suggest that FLT3 inhibition may represent a novel therapeutic strategy for infant ALL, and clinical testing is under way. An ongoing COG study (trial AALL0631) is evaluating the benefit of the addition of the FLT3 inhibitor lestaurtinib to an intensive chemotherapy backbone for patients with infant ALL.

Treatment and Outcomes
CONCLUSION AND FUTURE DIRECTIONS IN PEDIATRIC LYMPHOMA

Lymphomas are neoplasms caused by the malignant transformation of the constituent cells of the immune system. Combined, Hodgkin and non-Hodgkin lymphomas are the third most common malignancies in children and adolescents, with Hodgkin lymphoma being the most common cancer in people between the ages of 15 and 18 years.

The treatment of children and adolescents with lymphoma is one of the important success stories in pediatric oncology. The transformation of what were uniformly fatal diseases to those in which cure is the expectation occurred first for those with Hodgkin lymphoma and more recently for the majority of children with non-Hodgkin lymphoma. The understanding of normal and abnormal lymphoid biology has been critical to the develop systems for classification and for the evolution of disease-specific therapy.

This chapter reviews the clinical and pathologic features, including molecular and cellular biology, of the most common pediatric lymphoma subtypes and reviews the current strategies for evaluation and treatment.

LYMPHADENOPATHY

The child with lymphadenopathy poses a relatively common diagnostic challenge for the pediatrician. Over one third of 5-year-old children seen for well-child care and two thirds evaluated for a sick visit have palpable adenopathy.[1,2] In most children, lymph-node enlargement results from transient, self-limited infectious processes that resolve without sequelae. However, serious, life-threatening benign and malignant diseases may present with lymphadenopathy as the first manifestation. Thoughtful decision making is critical regarding further investigation, including which children require biopsy of their nodes for pathologic evaluation.

Various definitions of adenopathy have been described, including specific measurements in the radiologic literature. In general, adenopathy is defined as any node greater than 1 cm in dimension. Epitrochlear nodes are considered enlarged if they are greater than 0.5 cm, and inguinal nodes are enlarged if they are greater than 1.5 cm. Lymphadenopathy is considered localized if it involves a single node or single nodal area and generalized if it involves more than 2 noncontiguous nodal groups and may include hepatosplenomegaly. Chronic adenopathy is variably defined but in general can be considered as enlargement that persists for longer than 3 weeks.

Enlargement of lymph nodes results from expansion and recruitment of normal lymph node cells, expansion of abnormal immune cells, or infiltration of extrinsic cells. Certain considerations narrow the diagnostic possibilities in evaluation of the child with lymphadenopathy. Not all masses in children that appear to be lymphadenopathy represent enlarged lymph nodes; non–lymph-node masses that may mimic cervical lymphadenopathy include thyroglossal duct cysts and branchial cleft cysts. Evidence of recent or current upper respiratory infection and the presence of tender cervical adenopathy suggest inflammation as the cause. The presence of associated systemic symptoms, the chronicity of the adenopathy, and whether the adenopathy is generalized or regional are important considerations in the differential diagnosis. In addition, the age of the patient is important in considering the differential diagnosis, especially as it relates to potential malignant conditions. An abbreviated list of common causes of lymphadenopathy is presented in Box 53-1. More complete listings have been published elsewhere.[3,4]

Approach to the Patient

The management of the child with lymphadenopathy should be focused on obtaining clues to a diagnosis from the history, physical examination, and noninvasive testing, with the goals of ascertaining whether the lymphadenopathy is likely to be a manifestation of a serious illness and determining as early as possible in the workup whether the child should undergo lymph node biopsy. The history should include the duration of the adenopathy, associated symptoms, evidence of recent infection in the regions drained by the involved lymph node, exposure to illnesses, cats, or rodents, and current medications. The physical examination should be focused on ascertaining the location and number of enlarged nodes, their size, and their texture. Involvement of supraclavicular lymph nodes suggests mediastinal pathology and is usually associated with a serious disease mandating a prompt workup including a chest radiograph. In contrast the involvement of upper cervical lymph nodes is more likely to be the result of an upper respiratory tract infection.

For the child with generalized lymphadenopathy initial evaluation to be considered should include a complete blood count and a chest radiograph. Testing for possible infectious pathogens including viruses, fungi, and bacterial and mycobacterial agents should be considered. If no clues emerge, lymph node biopsy is likely indicated.

The workup of a child with localized or regional lymphadenopathy must be tailored to the individual child. Retrospective studies have attempted to identify those children with adenopathy who are more likely to have an underlying malignancy. Of children who underwent node biopsies, predictive factors for the etiology being malignancy included age older than 10 years, node size greater than 2.5 cm, and supraclavicular site.[5,6] Additional factors that were possibly associated included persistence of the node for longer than 6 weeks, having the node be “fixed” by palpation, and having more than one nodal area involved. In asymptomatic children whose adenopathy does not have high risk features, observation with careful measurement of lymph node size and possibly an empirical trial of antibiotic therapy is a reasonable strategy. If the nodes increase in size or fail to decrease to normal size after several weeks of observation, a lymph-node biopsy should be considered.

Box 53-1 **Causes of Lymphadenopathy**

INFECTION

Bacterial: *Staphylococcus aureus,* group A *Streptococcus, Bartonella henselae,* brucellosis, tularemia
Viral: Epstein-Barr virus, cytomegalovirus, human immunodeficiency virus, measles, rubella
Fungal: Histoplasmosis, coccidioidomycosis, *Cryptococcus*
Protozoan: Toxoplasmosis, malaria
Mycobacterial: Tuberculosis, atypical mycobacteria

AUTOIMMUNE DISEASE

Juvenile rheumatoid arthritis, systemic lupus erythematosus, serum sickness, autoimmune lymphoproliferative syndrome

STORAGE DISEASE

Niemann-Pick disease, Gaucher disease

DRUG REACTION

Phenytoin and others

MALIGNANCY

Lymphoma, leukemia, metastatic solid tumors, histiocytic disorders

MISCELLANEOUS

Sarcoidosis, Kawasaki disease, Kikuchi disease

Masses occurring in the mediastinum represent urgent and challenging diagnostic problems, whether the result of enlarged lymph nodes or of the involvement of extralymphatic tissues. Lymphomas account for a significant portion of anterior and middle mediastinal masses in children and adolescents. Their proximity to vital structures and their propensity to cause life-threatening symptoms from vascular or airway compromise mandate an expeditious, systematic approach involving close cooperation among the surgeon, radiologist, oncologist, anesthesiologist, radiotherapist, and pathologist. A differential diagnosis of mediastinal masses according to location within the mediastinum is shown in Box 53-2.

Box 53-2 **Differential Diagnosis of Mediastinal Masses**

ANTERIOR MEDIASTINUM

Lymphoma
Thymic cyst
Thymic “hyperplasia”
Benign teratoma
Malignant germ-cell tumor
Thymoma

MIDDLE MEDIASTINUM

Lymphoma
Tuberculosis
Histoplasmosis
Sarcoidosis

POSTERIOR MEDIASTINUM

Neuroblastoma
Ganglioneuroma
Neurofibroma
Sarcoma
Duplication cyst

EMERGENCIES IN PATIENTS WITH NEWLY DIAGNOSED LYMPHOMA

Children with lymphoma can have life-threatening findings such as respiratory distress and superior vena cava (SVC) syndrome caused by a mediastinal tumor, bowel obstruction from large abdominal masses, cranial nerve palsies, and paraplegia in the case of central nervous system (CNS) involvement and, in rare cases, disseminated intravascular coagulation. Patients may exhibit the metabolic derangements of acute tumor lysis syndrome (ATLS), although more often this problem arises after the initiation of therapy. Invasive diagnostic measures, especially those requiring anesthesia, can create emergencies for children with lymphomas.

A mediastinal tumor can cause respiratory distress as a result of tracheal or other large-airway compression. Patients often have cough, shortness of breath, and orthopnea. If there is considerable respiratory impairment, then all invasive diagnostic procedures need to be completed expeditiously. In these patients general anesthesia carries potential for substantial risks including inability to ventilate the child because of airway compression as well as swelling of the tracheal mucosa secondary to intubation, which may lead to worsening of critical constriction. Diagnostic procedures often need to be completed with local anesthesia alone. The least invasive procedure that will allow for attainment of diagnostic tissue should be undertaken.[7] In emergent situations, completion of staging (e.g., diagnostic lumbar puncture) may need to be deferred. Once tissue has been obtained, then initiation of steroids can be considered until pathologic diagnosis is complete. Very rarely for the patient with impending respiratory failure empirical therapy without specific diagnosis may needed. Cytoreduction with prednisone 60 mg/m^2/day and cyclophosphamide 100 to 200 mg/m^2/day or mediastinal radiation with doses of 10 to 15 Gy may provide a life-saving intervention.

In addition to respiratory impairment, mediastinal tumors can cause SVC syndrome by compression of the SVC and subsequent venous congestion. Patients have dilated neck veins, facial swelling, and discoloration. The life-threatening risk is from CNS venous strokes, often presenting as confusion or somnolence and less often as seizures or focal neurologic deficits. The tempo of progression of SVC syndrome in children tends to be much quicker in children than in adults as a consequence of more rapidly growing tumors. Again, in these patients expeditious evaluation and initiation of therapy is of critical importance.

Patients who have cranial nerve palsies and especially those with signs of incipient paraplegia also require urgent care. As in other pediatric malignancies, interventions may include surgical decompression, radiation, and chemotherapy. In general for children with lymphomas, which tend to be highly and quickly responsive to chemotherapy, initiation of therapy with prednisone or dexamethasone with or without cyclophosphamide is often the best approach. Clinicians should be aware that lumbar puncture in patients with bulky CNS disease may carry the risk of brainstem herniation. Urgent imaging should be considered before the procedure.

ATLS describes the metabolic derangements that occur with tumor-cell breakdown and is characterized by various combinations of hyperuricemia, hyperkalemia, and hyperphosphatemia with or without hypocalcemia and can lead to seizures, arrhythmias, renal failure, and death.[8] ATLS can be present before the initiation of treatment but more commonly occurs immediately after the initiation of chemotherapy. The incidence of ATLS differs among tumor types and depends primarily on the growth fraction, tumor mass, and chemotherapeutic sensitivity of the tumor. Adult and pediatric risk stratification algorithms for ATLS syndrome has been made and includes age, malignancy type, stage/lactate dehydrogenase (LDH) level, and renal function as predictive factors.[8] Patients with non-Hodgkin lymphoma (NHL) are at high risk, particularly those with advanced stage Burkitt lymphoma (BL), Burkitt leukemia, or lymphoblastic lymphoma (LL) with LDH greater than twice normal.

Vigorous hydration, alkalinization, and the administration of allopurinol, an inhibitor of xanthine oxidase, have been considered mainstays of prevention and treatment of ATLS and are aimed at the reduction of uric acid production and prevention of its precipitation in the kidneys. Evidence supporting the use of alkalization is controversial, and some contemporary guidelines do not recommend its use.[8] For patients considered at low risk, no specific intervention is required. For those at intermediate risk, careful monitoring of fluid and electrolytes is critical. Hyperhydration and allopurinol are almost always sufficient.

For those with higher risk for tumor lysis or who have evidence of the syndrome before the initiation of therapy, rasburicase should be considered. This agent is a recombinant urate oxidase that catalyzes the conversion of uric acid to allantoin. Allantoin is an inactive metabolite that is five to ten times more soluble than uric acid, so renal excretion is facilitated. A single dose will result in the rapid reduction in uric acid levels in patients with hyperurecemia.[9] It is contraindicated in patients with a history of glucose-6-phosphate dehydrogenase (G6PD) deficiency because of substantial risks of precipitating severe hemolysis. In a systematic review of published randomized trials, rasburicase was highly effective at reducing elevated uric acid, although the impact on mortality and renal failure was unclear.[10] In a French study of children with advanced stage B-cell NHL that incorporated the use of rasburicase, the incidence of need for dialysis during the first days of treatment was only 2.6% compared with 16% and 23% in other cooperative studies using the same French protocol that used only allopurinol.[11]

In some patients, even with optimal ATLS care renal function is insufficient and early hemodialysis should be instituted. This situation may occur because of direct infiltration of the kidneys, obstruction of the urinary tract caused by lymphomatous compression, established urate or calcium phosphate nephropathy, or a combination of these conditions.

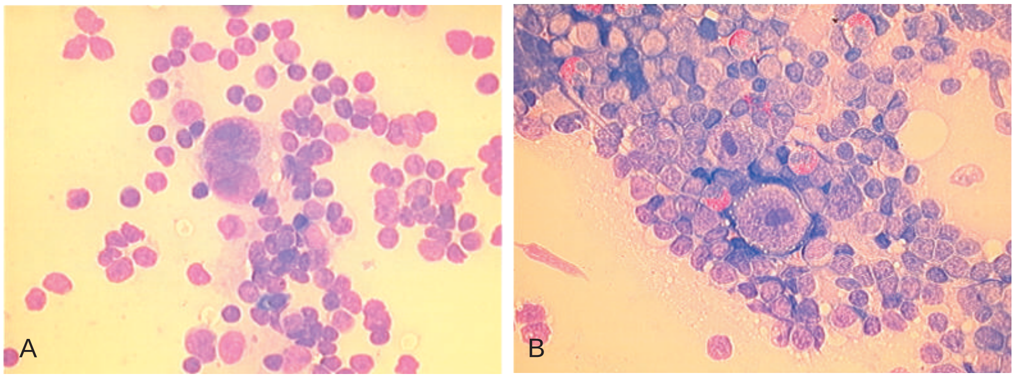

Figure 53-1 **A,** Reed-Sternberg cell. **B,** Hodgkin cell. Reed-Sternberg cells are large cells with abundant slightly basophilic cytoplasm and have at least two nuclear lobes or nuclei containing a prominent inclusion-like eosinophilic nucleolus. Mononuclear variants are known as Hodgkin cells and often have a more intense basophilic cytoplasm.

HODGKIN LYMPHOMA

Hodgkin lymphoma was first described in 1832 by Thomas Hodgkin as a disorder characterized by a peculiar enlargement of the absorbent (lymphatic) glands and spleen and was named in 1865 by Sir Samuel Wilks.[12,13] Sternberg and Reed, in 1898 and 1902, respectively, are credited with the first definitive and thorough description of the binucleate or multinucleated giant cells that when present, are considered pathognomonic of this disorder (Fig. 53-1).[14,15] The malignant nature of the disease was proven when Seif and Spriggs confirmed the clonal origin of the malignant cell by cytogenetic analysis.[16]

Before 1960 Hodgkin lymphoma was an almost uniformly fatal disease. In the 1960s investigators at Stanford and elsewhere developed the use of megavoltage radiotherapy and defined treatment fields including mantle, inverted Y, total nodal, and total lymphoid irradiation.[17] Subsequently in the late 1960s and early 1970s the first randomized trials were initiated.[18,19] Concurrently chemotherapy agents were being investigated. After the observation of the lympholytic effect of nitrogen mustard, this and other agents were used individually in the attempt to treat patients with leukemia and lymphoma. A major step forward toward the use of chemotherapy for Hodgkin lymphoma was the introduction of the four-drug combination of mechlorethamine, vincristine (Oncovin), procarbazine, and prednisone (the MOPP regimen), which led to substantial rates of cure in previously incurable patients.[20]

Over the next 20 years, standard therapy included clinical and surgical staging including laparotomy and splenectomy, as well as extended field radiation with doses of 36 to 44 Gy with or without combination chemotherapy. The probability of cure in children and adolescents using this strategy approached 90%.[21] Early on, however, late effects of therapy were noted. The first to be observed was the impact on musculoskeletal growth of young children receiving high-dose extended field radiation.[22] Subsequently, the long list of therapy-related late effects emerged to include second malignancies, serious cardiac and pulmonary compromise, infectious complications, and sterility.[23] For the last two decades the focus of the development of care for patients with Hodgkin lymphoma has been to maximize the probability of long-term, disease-free survival but to do so while minimizing risks of late effects.

Unlike the complex evolution of classification systems for NHL, the systems used for Hodgkin lymphoma have been more straightforward. The Rye modification of the Lukes-Butler system of classification of Hodgkin disease was universally accepted for 25 years and formed the basis for the current World Health Organization (WHO) classification.[24,25] Studies of the biology and clinical course of the disease have shown that Hodgkin lymphoma should be subdivided into two entities, classic Hodgkin lymphoma (CHL) and nodular lymphocyte–predominant Hodgkin lymphoma (NLPHL) (Table 53-1). The two entities will be discussed separately in the next sections.

Classic Hodgkin Lymphoma

Pathologic Features

CHL is characterized by the presence of mononuclear Hodgkin and multinucleated Reed-Sternberg cells. Hodgkin and Reed-Sternberg cells are usually in the minority, residing in a reactive infiltrate of a variable mixture of nonneoplastic lymphocytes, eosinophils, neutrophils, plasma cells, fibroblasts, and collagen fibers present in response to cytokines produced by the tumor.[26] The Reed-Sternberg cells are large cells with abundant, slightly basophilic cytoplasm and have at least two nuclear lobes or nuclei containing a prominent inclusion-like eosinophilic nucleolus. Diagnostic Reed-Sternberg cells must have at least two nuclei in two separate lobes. Mononuclear variants are termed *Hodgkin cells* and often have a more intense basophilic cytoplasm. Microdissection techniques have enabled the isolation of Reed-Sternberg cells from frozen sections and the investigation of their lineage commitment. In more than 98% of cases, Reed-Sternberg cells are B cells, as defined by monoclonal immunoglobulin gene rearrangements.[27] Only a few cases have shown clonal T-cell receptor (TCR) gene rearrangement in the Reed-Sternberg cells, suggesting T-cell origin.[28] Reed-Sternberg cells of CHL express the B-lineage

TABLE 53-1 Pathologic and Clinical Features of Classic and Nodular Lymphocyte Predominant Hodgkin Lymphoma in Children and Adolescents

	CHL	NLPHL
Percentage of patients	92%-95%	5%-8%
Histologic hallmark	Reed-Sternberg cell	Lymphocyte-predominant cells (also called *popcorn cells*)
Immunophenotype	CD15 and CD30 common, CD20 rare	CD15 and CD30 rare, CD20 common
EBV association	Yes in 40%	Negative
Percentage male	50%	75%
Peak incidence	15-20 years	13 years
Disease at presentation	Majority with stage II or greater; mediastinal involvement common	Majority with stage IA or IIA; mediastinal involvement uncommon

Modified from Shankara A, Saw S: Nodular lymphocyte-predominant Hodgkin lymphoma in children and adolescents: a comprehensive review of biology, clinical course, and treatment options. Br J Haematol *159:288–298, 2012.*

CHL, Classic Hodgkin lymphoma; *EBV,* Epstein-Barr virus; *NLPHL,* nodular lymphocyte-predominant Hodgkin lymphoma.

antigens CD20 and CD79a in variable proportions, whereas the B-cell–specific activator protein (BSAP), a product of the *PAX5* gene, is expressed in about 90% of cases.[29,30] Reed-Sternberg cells are almost invariably positive for the CD30 antigen[29] and usually express the CD15 antigen, whereas the expression of the epithelial membrane antigen (EMA) is rare. In Epstein-Barr virus (EBV)–positive cases of CHL, the Reed-Sternberg cells express the EBV latency type II pattern latent membrane (LMP) protein 1 and Epstein-Barr nuclear antigen (EBNA) 1, but without EBNA2.[31]

Based on the characteristics of the reactive infiltrate and the morphology of the Reed-Sternberg cells, four subtypes of classic Hodgkin lymphoma are distinguished in the WHO classification[25,32]: lymphocyte-rich Hodgkin lymphoma (LRHL), lymphocyte-depleted Hodgkin lymphoma (LDHL), mixed-cellularity Hodgkin lymphoma (MCHL), and nodular sclerosis Hodgkin lymphoma (NSHL). The immunophenotypic and genetic features of the Reed-Sternberg cells are identical in these histologic subtypes, whereas they differ in clinical features and association with EBV. CHL is associated with overexpression and an abnormal pattern of cytokines and chemokines and their receptors by Reed-Sternberg cells and the cells of the reactive background.[33,34] The abnormal cytokine and chemokine expression most likely accounts for the abundant admixture and pattern of inflammatory cells in CHL lesions as well as for distinct clinical features.

The NSHL subtype is characterized by a nodal growth pattern with collagen bands that surround at least one nodule, the formation of clusters of Reed-Sternberg cells, and so-called *lacunar cells* (mononuclear Hodgkin cells with only moderately prominent nucleoli).[26,35] NSHL can be grade 1 or 2, mainly depending on the number of Reed-Sternberg cells in distinct nodules.[36] The EBV-encoded LMP1 antigen is less commonly expressed than in other subtypes.

The MCHL subtype is characterized by scattered classic Reed-Sternberg cells in a diffuse or vaguely nodular mixed inflammatory background without sclerosis. Partial involvement of the lymph node can be observed in MCHL, described as *interfollicular disease.* The EBV-encoded LMP1 antigen is more commonly expressed than in NSHL.

The LRHL and LDHL subtypes are relatively rare in children.[37,38] The LRHL subtype contains scattered Reed-Sternberg cells and a nodular or diffuse background of small lymphocytes but with an absence of neutrophils and eosinophils. The LDHL subtype is a diffuse form of CHL, rich in Reed-Sternberg cells and/or depleted of non-neoplastic lymphocytes and is often sarcomatoid in appearance.

In some patients, distinction between true Hodgkin lymphoma and certain subtypes of NHL can be difficult. Grey-zone lymphomas are those that do not fit into a single disease entity. The WHO classification includes the entity of "B-cell lymphoma, unclassifiable with features intermediate between diffuse large B-cell lymphoma (DLBCL) and classic Hodgkin lymphoma," although this entity is exceptionally rare in children.[25]

Molecular and Cellular Biology

The cell of origin of the malignant cells in CHL was long a matter of controversy because of the low incidence of Reed-Sternberg cells in the tumors and their unusual immunophenotype in that they lack expression of immunoglobulins and other B-cell markers; rather, they express markers characteristic of dendritic cells, granulocytes, monocytes, and T cells.[40] However, the identification of immunoglobulin gene rearrangement[27,41,42] and somatic hypermutation in microdissected Reed-Sternberg cells in almost all cases of CHL has demonstrated that these cells derive from postgerminal B cells. In addition these studies have demonstrated that about 25% of CHL cases carry crippling immunoglobulin-gene rearrangements that destroy the function of the immunoglobulin protein.[27,41] These nonfunctional rearrangements typically induce rapid apoptosis in normal B cells, suggesting that Hodgkin lymphoma may originate from germinal-center B cells that have escaped apoptosis. Analysis of TCR rearrangements has shown that despite the common expression of T-cell markers, CHL originates from T cells in only 1% to 2% of cases.[28]

In NLPHL, the malignant popcorn cells show expression of B-cell markers such as CD20 and CD79a, suggesting a B-cell origin for these tumors as well. As in CHL, the analysis of immunoglobulin genes in microdissected tumors has shown clonal and somatically mutated gene rearrangements.[27,43] In addition, 50% of cases have shown evidence of ongoing somatic hypermutation, which strongly suggests that they derive from germinal center B cells.[27]

Mechanisms of Transformation. EBV has been associated with the pathogenesis of CHL, which shows EBV infection of the Reed-Sternberg cell in 40% of the cases in the Western world and 90% in Central America.[44-46] Importantly, EBV can immortalize human B cells in vitro, and Reed-Sternberg cells are clonally infected by EBV, which suggests that viral infection occurs early in the pathogenesis of the disease.[47] EBV positive Reed-Stenberg cells express EBNA1, LMP1, and the *LMP2a* viral gene, which is characteristic of the viral latency II stage. Mechanistically, LMP1 mimics an active CD40 receptor and can activate the nuclear factor κB (NF-κB) pathway, which is constitutively active in Hodgkin lymphoma (see later).[48] LMP2, a second viral gene product, mimics B-cell receptor signaling and might play a role in rescuing Reed-Sternberg cells from apoptosis with immunoglobulin-crippling mutations.[49] Cytogenetically, Reed-Sternberg cells often show aneuploidy and chromosomal abnormalities, with 20% of the cases harboring chromosomal translocations involving the immunoglobulin loci, a hallmark of many B-cell lymphomas.[50,51]

The most prominent molecular abnormality found in Hodgkin lymphoma is the constitutive activation of the NF-κB pathway. NF-κB functions as an important survival-signaling pathway in B cells in response to the activation of members of the tumor necrosis factor (TNF) receptor family (CD30, CD40). In Hodgkin lymphoma, somatic mutations in different elements of the NF-κB pathway keep it constitutively activated. Thus the *REL* gene, which encodes an NF-κB component, is amplified in the of 30% of the cases.[52,53] Gains of NF-κB–inducing kinase (NIK), a positive regulator of the alternative NF-κB pathway, are also commonly found in Reed-Sternberg cells,[54,55] and translocations and amplifications resulting in overexpression of the *BCL3* gene in Reed-Sternberg cells has been described.[56] Moreover, mutations of the gene-encoding NF-κB inhibitors IKBA and IKBE are found in 10% to 20% of cases of Hodgkin lymphoma.[57-59] Most significantly *TNFAIP3*, which encodes A20, a ubiquitin-modifying enzyme involved in the negative regulation of NF-κB signaling, harbors loss of function mutations and deletions in almost 45% classic Hodgkin lymphomas.[60,61] Notably, *TNFAIP3* mutations and deletions are more common in EBV-negative tumors and are rarely found in lymphocyte-predominant Hodgkin lymphomas.[61,62] Finally, activation of TNF signaling by the microenvironment and activation of NF-κB by the LMP1 EBV oncogene may also contribute to aberrant NF-κB signaling.

Gene amplifications involving the *JAK2* locus have been described in about 20% of CHL cases, suggesting a role for *JAK2* activation in the pathogenesis of this disease.[63] In addition, rearrangements of *JAK2* including a recurrent *SEC31A–JAK2* translocation have been described in rare cases of Hodgkin lymphoma.[64] Moreover, loss of function mutations in *SOCS1*, a negative regulator of Janus kinase (JAK)–signal transducer and activator of transcription (STAT) signaling are present in about 50% of classic and lymphocyte-predominant Hodgkin lymphomas and are associated with increased levels of JAK signaling.[65,66]

Translocations involving the major histocompatibility complex (MHC) class II transactivator gene *CIITA*, resulting in impaired MHC class II expression, are found in 15% of CHL cases[67] and seem to be associated with unfavorable prognosis.[68] In contrast to CHL, the malignant cells of the lymphocyte-predominant type of Hodgkin lymphomas are always EBV-negative, and there is little information on the molecular lesions implicated in the pathogenesis of this group. Chromosomal translocations involving the *BCL6* oncogene can be detected in 30% of cases.[69] *BCL6* is a zinc-finger transcription repressor that functions as a master regulator of germinal-center formation and drives B-cell transformation. Thus *Bcl6*-null mice fail to generate germinal centers in response to immunization, and deregulated expression of *Bcl6* induces B-cell lymphomas in mice.[70] Mechanistically, aberrant expression of *BCL6* in lymphoma hijacks the role of *BCL6* in the control of B-cell activation, differentiation, deoxyribonucleic acid (DNA) damage response, cell-cycle arrest, and apoptosis.[70] Finally, about 40% of lymphocyte-predominant Hodgkin lymphoma tumors show mutations in *SOCS1,*[66] but mutations in *TNAIP3* and *NFKBIA* are rare despite strong NF-κB activity.[62,71]

Cellular Microenvironment: Cytokines and Chemokines. The cellular and cytokine microenvironment surrounding the lymphoid cells in Hodgkin lymphoma plays an essential role in the pathogenesis of this disease. In particular, the expression of soluble factors and their receptors by malignant cells and the reactive microenvironment seems not only to mediate the inflammatory characteristics observed in the histology of Hodgkin lymphoma, but also to contribute to the proliferation and survival of the malignant clone. Thus the cellular microenvironment supports and is supported by a network of cytokines secreted in autocrine and paracrine loops that are essential for the proliferation of Reed-Sternberg cells and the maintenence of a favorable inflammatory environment rich in regulatory T cells (Tregs) and eosinophils.

Both interleukin (IL) 13 and the IL-13 receptor IL-13RA1 are expressed in Hodgkin lymphoma and constitute an important autocrine loop for Reed-Sternberg cells.[72,73] Other cytokines expressed in Hodgkin lymphoma and thought to influence survival of these cells include IL-4, IL-6, IL-7, IL-9, and IL-15.[33,34]

The vast majority of cells in a tumor biopsy of Hodgkin lymphoma are not malignant cells but represent an inflammatory-like cellular infiltrate composed mainly of CD4+ T lymphocytes intermixed with macrophages, eosinophils, plasma cells, and fibroblasts. Most lymphocytes present in this infiltrate are Tregs, which play an important role in protecting the tumor's Reed-Sternberg cells from cytotoxic T cells involved in antitumor immune surveillance.[49]

In contrast with the abundance of Tregs, Th1 CD4+ T cells and CD8+ cytotoxic T cells are rare in Hodgkin lymphoma biopsies and are not detected in the immediate proximity of Reed-Sternberg cells. The recruitment of cells involved in immune tolerance and the exclusion

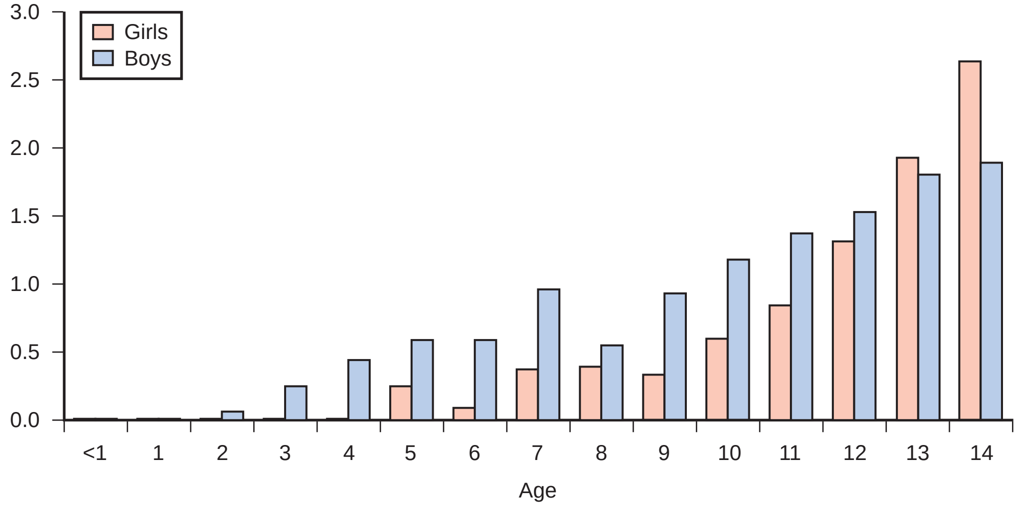

Figure 53-2 Age- and gender-specific incidence rates (per 100,000) of Hodgkin lymphoma during childhood in Germany, 2000 to 2004. *(Modified from Kaatsch P, Spix C:* Annual report, 2005: German Childhood Cancer Registry, *Mainz, Germany, 2007, Institut für Medizinische Biometrie, Epidemiologie, und Informatik, p 52.)*

of lymphoid cells responsible for antitumor immune responses are explained by the expression of Reed-Sternberg cells of pro-Th2–associated cytokines, such as IL-4 and IL-13, and anti-Th1 or CD8 cytokines, such as IL-10 and transforming growth factor (TGF) β.[49] The secretion of these immunosuppressive cytokines creates an immune-privileged microenvironment, allowing the tumor cells to avoid immune surveillance and T-cell–mediated apoptosis.

One of the most prominent features of Reed-Sternberg cells is the expression of CD30. Although coexpression of CD30 and its respective receptor CD153 initially suggested an autocrine mechanism promoting the proliferation of Reed-Sternberg cells via NF-κB, it is now well established that the activation of CD30 is primarily a CD153-independent process.[74] Two additional members of the TNF receptor family, CD40 and receptor activator of nuclear factor κB (RANK), are expressed in Reed-Sternberg cells. Activation of CD40 seems to be mediated by the expression of CD40 ligand (CD40L) on T lymphocytes surrounding the Reed-Sternberg cell.[75,76] Importantly, soluble CD40L induces proliferation and blocks CD95-induced apoptosis in Reed-Sternberg cells.[75-77] Other factors that help rescue Hodgkin and Reed-Sternberg cells from an immunologic attack include the expression of the PD1 ligand and secretion of IL-10, TGF-β, and galectin 1 by the Reed-Sternberg cell,[78-82] as well as inhibition of cytotoxic T cells by regulatory T cells (Tregs).[78] Activation of RANK and osteoprotegerin, a member of the TNF-receptor superfamily, is triggered by the autocrine expression of RANK ligand (RANKL) in Reed-Sternberg cells.[83] Activation of RANK promotes NF-κB activation and contributes to the maintenance of an inflammatory microenvironment by promoting interferon gamma (IFN-γ) and IL-13 secretion.[49] Overall, the activation of TNF receptors by different mechanisms seems to play an important role in promoting the survival of the Reed-Sternberg cell.

Epidemiology and Causative Factors

The epidemiology of Hodgkin lymphoma is complex, with variation across geographic regions and with age, sex, and socioeconomic status. Data from cancer incidence surveys conducted in five continents have suggested that Hodgkin lymphoma has a bimodal peak at ages 15 to 34 years and a second peak in those older than 60 years.[84] In Asian populations the overall incidence is only half that of the incidence in Europe.[85,86] In all regions, Hodgkin lymphoma occurs rarely in children younger than 5 years of age (Fig. 53-2).

Hodgkin lymphoma occurring in patients younger than 15 years of age, referred to as *childhood Hodgkin lymphoma,* has several unique features compared with the more common disease of older adolescents and young adults. In childhood disease there is a 2 to 3:1 male preponderance, whereas in older patients the disease is almost equal in males and females.[87] Within the younger age group, mixed cellularity and nodular lymphocyte-predominant histologies are more common.[88] In addition, in childhood Hodgkin lymphoma increasing family size and lower socioeconomic status are risk factors for disease. Conversely, in Hodgkin lymphoma in adolescents and young adults, higher socioeconomic status and smaller family size are risk factors for disease.[89,90]

The role of EBV as an etiologic agent for Hodgkin lymphoma has been the source of much study.[91] In 1966 MacMahon[92] was the first to suggest an infectious cause of Hodgkin lymphoma, and in 1974 Rosdahl and colleagues[93] reported an increased risk of Hodgkin lymphoma in people with a history of infectious mononucleosis.[87] Molecular studies identified monoclonal EBV genomes in Reed-Sternberg cells, implying that they were infected before malignant transformation.[94,95] Subsequent studies showed EBV genome sequences associated with Reed-Sternberg cells in 59% of cases.[96] The proportion of EBV-positive Hodgkin lymphoma cases varies, however, according to geographic region, age, and histologic subtype. The proportion of EBV-positive Hodgkin lymphoma cases is higher in children than adults. It is most prevalent in mixed cellularity histology and more common in boys. The incidence is higher in the developing world including parts of Africa, Asia, and South America, with an incidence of EBV-positive Hodgkin lymphoma as high as 90% in Peru.[97]

Familial aggregation of Hodgkin lymphoma was first described by Razis and coworkers in 1959[98] and is now well documented.[99-102] The familial risk of Hodgkin lymphoma ranks among the highest in the population-based Swedish Family Cancer Database.[103] In an analysis of 28 reports of familial Hodgkin lymphoma there is only one major peak between 15 and 34 years of age for familial Hodgkin lymphoma instead of the classic bimodal age distribution of sporadic Hodgkin lymphoma.[104] This corresponds to the findings of two large studies of an increased sevenfold risk in siblings of cases diagnosed at ages younger than 45 and 35 years of age, respectively, but little or no increased risk in siblings of cases diagnosed at older ages.[105,106] Strong evidence for a role for genetic susceptibility was provided by the finding that monozygotic twins of patients with Hodgkin lymphoma have a 99-fold increased risk, whereas no increased risk in dizygotic twins was observed.[99]

Familial aggregation of Hodgkin lymphoma may in part reflect inherited abnormalities of the immune response. A familial or personal history of autoimmune conditions and sarcoidosis is associated with an increased risk for Hodgkin lymphoma.[107,108] A 51-fold increased risk for Hodgkin lymphoma was found in kindreds predisposed to autoimmune lymphoproliferative syndrome, a disorder of lymphocyte homeostasis usually associated with germline *FAS* gene mutations.[109] In patients with ataxia-telangiectasia mutation (ATM), the risk of Hodgkin lymphoma was increased, but its risk was much lower than the risk of NHL.[110] In 1975 Svejgaard and coworkers first described an association of certain human leukocyte antigen (HLA) loci with an increased risk of Hodgkin lymphoma, suggesting a disease susceptibility gene within or near the histocompatibility region on chromosome 6.[111,112] Since then, numerous studies have confirmed the association of particular HLA loci in the susceptibility to Hodgkin lymphoma, including HLAs A1, B5, B8, B15, B27, B35, and B37.[113] In a large study on familial Hodgkin lymphoma, Chakravarti and colleagues[114] have found strong evidence for a recessive mode of inheritance for susceptibility to Hodgkin lymphoma, and approximately 60% of associations were caused by an HLA-linked susceptibility gene. Recent genetic studies have identified disruption of *KLHDC8B* in the germline of a family with several cases of Hodgkin lymphoma[115] and a germline frameshift mutation in the *NPAT* gene in a family with four cases of NLPHL.[116] Finally a genome-wide association study has identified risk loci at 2p16.1 (*REL*), 8q24.21 (*PVT1*), and 10p14 (*GATA3*) and confirmed the strong HLA association with this disease.[117]

Clinical Characteristics

The most common clinical presentation of Hodgkin lymphoma in children and adolescents is a persistently enlarged node in the cervical or supraclavicular region. Characteristically the lymph nodes involved with Hodgkin lymphoma are not painful and have a "rubbery" firmness on palpation. Enlarged nodes have often been present for weeks or months, increasing and decreasing in size irrespective of whether antibiotic therapy has been given. Although the majority of patients have painless cervical adenopathy, the clinical presentation varies considerably, ranging from life-threatening airway compression to the coincidental detection of an enlarged node during an otherwise routine examination. Approximately 80% of children have disease in one or both sides of the upper or lower neck. Of those with cervical adenopathy, more than two thirds have intrathoracic disease, most commonly in the anterosuperior mediastinum, paratracheal, and tracheobronchial lymph node groups. Pulmonary parenchymal involvement is rarely observed in the absence of hilar disease. Pleural effusions are uncommon; they are usually an indication of lymphatic obstruction from bulky central disease rather than a sign of advanced-stage disease. Pericardial effusion may occur in cases with pericardial involvement and occurs most often in the setting of bulky mediastinal disease.[118] Hodgkin lymphoma has a strong tendency for contiguous spread along adjacent lymph-node regions. Although about 30% of patients have supradiaphragmatic and infradiaphragmatic disease, Hodgkin lymphoma limited to infradiaphragmatic sites is rare.[38]

Systemic symptoms including fatigue and anorexia are common in patients with Hodgkin lymphoma. At the time of diagnosis, approximately 30% of patients have constitutional signs referred to as *B symptoms* and defined as the presence of fever (temperature higher than 38° C [100.4° F]) for 3 consecutive days, drenching night sweats and unexplained body weight loss of 10% or more over the preceding 6 months. Classically the fever associated with Hodgkin lymphoma, called the *Pel-Epstein fever,* occurs in the evening and becomes more pronounced with time. Severe and unexplained pruritus is associated with Hodgkin lymphoma, sometimes preceding the development of adenopathy. A poorly understood and relatively unusual sign of Hodgkin lymphoma is pain at the sites of disease with alcohol ingestion.

Laboratory findings are often nonspecific with mild anemia and elevated erythrocyte sedimentation rate (ESR) being the most common findings. Nonspecific hematologic laboratory findings include neutrophilia, monocytosis, lymphopenia, and eosinophilia. Acute-phase reactants including C-reactive protein, ferritin, and serum copper may be elevated. High levels of alkaline phosphatase can be associated with bone involvement.

Rarely patients with Hodgkin have findings suggestive of paraneoplastic syndromes such as nephritic syndrome, polymyositis, idiopathic cholestasis and autoimmune hemolytic anemia, neutropenia, and thrombocytopenia, or combinations of these. Limbic encephalitis or subacute cerebellar degeneration have also been reported as very rare paraneoplastic syndromes in patients with Hodgkin lymphoma.[119]

At the time of diagnosis patients may exhibit altered immune function characterized by reduced cellular immunity, whereas humoral immunity is usually relatively intact.[120] The nature of the immune defect is unclear. The severity of the impairment increases with advanced stage, disease progression, and recurrence and after treatment with radiotherapy and chemotherapy. T-cell deficits may persist for a prolonged period in successfully treated patients.

Diagnosis and Staging

Biopsy to provide pathologic tissue for examination is required for the diagnosis of Hodgkin lymphoma. Excisional biopsy of an enlarged node is preferred. Samples from needle biopsies are often insufficient for the diagnosis of Hodgkin lymphoma because of the importance of the information provided by the nodal architecture and background stroma, as well as the need to identify the relatively rare Reed-Sternberg cell. In a case series, one third of children who ultimately were diagnosed with Hodgkin lymphoma and who underwent core needle biopsies of their mediastinal masses were not able to be diagnosed from these initial samples.[121] Needle biopsy should be restricted to situations in which surgery and general anesthesia may carry undue risks for the patient. If needle biopsy is performed, multiple biopsy samples should be taken to augment diagnostic potential.

The purpose of a staging evaluation is to identify all sites and characteristics of Hodgkin lymphoma in each patient to permit accurate stratification of therapy based on risk, the definition of areas to be included in potential radiation fields, and to inform follow-up imaging studies. Table 53-2 gives an overview of suggested evaluations.

TABLE 53-2 Recommended Investigations in Children and Adolescents with Hodgkin Lymphoma

Laboratory studies	1. Complete blood count (CBC) 2. Erythrocyte sedimentation rate (ESR) 3. Renal and liver function studies 4. Albumin 5. Lactate dehydrogenase (LDH) 6. Alkaline phosphatase
Imaging	1. Chest x-ray 2. Computed tomography (CT) of neck and chest 3. CT or ultrasound or magnetic resonance imaging (MRI) of the abdomen and pelvis 4. Positron emission tomography (PET) (if available) 5. Bone scan (if no PET available and focal bony pain or advanced stage disease)
Other investigations	1. Bone marrow biopsy, except stage 1A and 2A, and possibly those without evidence of bone-marrow involvement by PET (see below) 2. Selective biopsy for sites of potential involvement that are ambiguous and whose clarification is important for staging and treatment planning
Other pretherapy considerations	1. Assessment of pulmonary function 2. Assessment of cardiac function 3. Assessment of thyroid function 4. Consideration of fertility preservation (sperm banking) 5. Consideration for need of stable intravenous access

A plain film of the chest is useful in providing preliminary information about mediastinal involvement and is an essential evaluation in a patient who will undergo anesthesia for cervical node biopsy (Fig. 53-3). Computed tomography (CT) of the neck, chest, abdomen, and pelvis are standard initial staging evaluations.[122] In the past, imaging of the neck was considered not necessary given the ability to detect cervical node by physical examination. Imaging of the neck, however, can be of significant importance to current care, because it allows for the most accurate radiation field planning, avoiding potential overtreatment of the neck, and providing baseline data for the measurement of disease response.[23] CT of the chest provides detailed information about sites of disease involvement including the mediastinum, pulmonary parenchyma, pleura, and pericardium. Sites of disease in the abdomen and pelvis are visualized with CT done with oral and intravenous (IV) contrast. Alternatively, magnetic resonance imaging (MRI) or ultrasound can also be used for staging abdominal and pelvis disease.

Functional nuclear imaging is an important component to initial staging though perhaps has an even more significant role in assessment of disease response (see later). Gallium-67 imaging has largely been replaced by 18-fluorodeoxyglucose positron emission tomography (FDG-PET) because of increased sensitivity and specificity.[123,124] Increased ^{18}F-FDG uptake in lymphoma is based on elevated glycolysis and the longer residence time of ^{18}F-FDG in malignant cells compared with most normal tissues.[125] Numerous studies in adults with Hodgkin lymphoma have demonstrated that PET is able to detect an additional number of Hodgkin lymphoma lesions compared with conventional imaging studies, in particular CT and bone marrow biopsy, resulting in a modification of staging in 15% to 20% of patients, with an impact on disease management in 5% to 15% of cases.[126] The data in children are more limited.[127,128] A review of a single-center experience showed that the findings from the diagnostic FDG-PET were more sensitive than conventional imaging and that the findings altered the involved-field radiation treatment fields in 17% of patients.[129] Prospective studies are required to assess whether FDG-PET done at the time of diagnosis has on impact on outcome or on treatment burden.

Historically, surgical staging including splenectomy was considered standard for patients with Hodgkin lymphoma. Staging splenectomy is associated with significant risks. In the German-Austrian experience of 1181 children with Hodgkin lymphoma, the survival was poorer for children younger than age 10 years because of episodes of infection and death caused by sepsis in splenectomized children.[130,131] With the availability of cross-sectional imaging techniques, routine staging laparotomy has now been abandoned. In the relatively rare circumstance of imaging findings that are ambiguous in defining

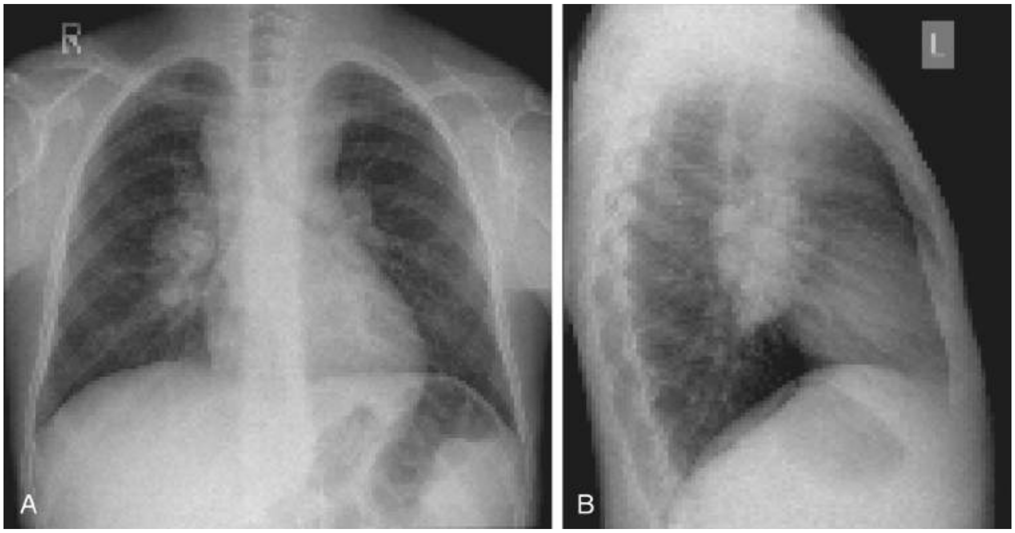

Figure 53-3 Chest x-ray of a patient with Hodgkin lymphoma and involvement of the mediastinal nodes and hilum.

disease involvement or noninvolvement, and when this information affects therapeutic decision making and in particular radiation fields, then staging biopsy may still be warranted.

Until recently bone marrow biopsy has been considered a standard component of the initial staging evaluation for any child with cytopenias at presentation and all patients except for those with stage 1A or 2A disease. Retrospective investigations have suggested that the impact of the findings from diagnostic bone marrow biopsies had a minimal effect on patient-risk assignment and subsequent therapy.[132] FDG-PET is a sensitive and specific method for detection of bone marrow disease. Two recent studies provide data to support the idea that FDG-PET can replace bone marrow biopsies for staging purposes[133,134] in an analogous fashion to cross-sectional imaging of the abdomen replacing staging laparotomy in the past.

The Ann Arbor staging classification for Hodgkin lymphoma, adopted in 1971, was based on the recognized orderly spread of the disease between contiguous lymph nodes, which predominates until late in the course of the disease (Table 53-3).[135] The distinct lymph node regions recognized by the Ann Arbor classification system are shown in Figure 53-4. The substage classifications A, B, and E amend each stage based on distinct features. Stage A designates asymptomatic disease; B indicates the presence of any one of the three B symptoms as defined in Table 53-3; and extralymphatic disease is designated as E, referring to limited extranodal extensions that easily can be encompassed within a radiotherapy portal. Extralymphatic disease is further designated as L (lung), P (pleura), and O (osseous) according to this system. The decision to classify extralymphatic disease either as substage E or as stage IV is based on the clinician's judgment and often depends on whether the extralymphatic disease can be adequately covered in a radiotherapy treatment portal. Multiple E lesions are automatically considered to be stage IV.

Treatment

Centers treating children with Hodgkin lymphoma should have extensive experience and a dedicated multidisciplinary team, including a pediatric surgeon, radiation oncologist, pediatric oncologist, pathologist, and diagnostic radiologist. If such a team is not available at the

TABLE 53-3 Ann Arbor Staging Classification for Hodgkin Lymphoma

Stage	Description
I	Involvement of a single lymph-node region (I) or a single extralymphatic organ or site (I_E)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized contiguous involvement of only one extralymphatic organ or site and its regional lymph node(s) on the same side of the diaphragm (II_E)
III	Involvement of lymph-node regions on both sides of the diaphragm (III), which may also be accompanied by involvement of the spleen (III_S) or by localized contiguous involvement of an extralymphatic organ or site (III_E) or both (III_{SE})
IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues, with or without associated lymph-node involvement
Designations Applicable to Any Stage	
A	No B symptoms
B	B symptoms, defined as presence of fever (>38° C [100.4° F]) for 3 consecutive days, drenching night sweats, or unexplained loss of 10% or more of body weight in the preceding 6 months
E	Involvement of a single extranodal site that is contiguous or proximal to the known nodal site

facility at which the child is initially seen, prompt referral to a comprehensive childhood cancer center is essential.

Prognostic Factors/Stratification of Treatment. As with other malignancies, prognostic factors are useful as tools for defining risk groups for stratification of treatment intensity. For patients with Hodgkin lymphoma this translates into both the choice of chemotherapeutic regimen and the use of radiotherapy. The stage of disease is a strong prognostic factor and widely used for risk stratification that has been used in all major cooperative groups.[37,130,136] Apart from the stage of disease, a number of factors have been reported to be associated with the risk of treatment failure, including the presence of B symptoms, histologic subtype, bulky disease, gender, anemia, ESR, and evidence of latent EBV infection, some of which have lost significance with improvements in therapy.[137,138] The prognostic value of these variables has not been consistent across studies, in part related to treatment prescribed. For example, mediastinal bulky disease—defined as a mass larger than one third of the maximum chest diameter—was associated with increased risk for relapse in some studies but not in the German-Austrian trial DAL-HD90. However, in this protocol patients with a larger residual mass at the end of chemotherapy received a boost dose in addition to the involved field irradiation.[130,139] Similarly, male gender had an adverse impact on outcome in that trial. For boys, however, procarbazine was partially replaced by etoposide, and girls received a full dose of procarbazine. Race and ethnicity have been identified as risk factors in some pediatric cancers. In a single-center retrospective review, African-American children had an inferior event-free survival (EFS) rate but an identical overall survival (OS) as compared with white children.[140]

The risk-group definitions used in selected clinical trials are described in Table 53-4. In general in addition to stage, disease bulk and presence of B symptoms are the factors used. The kinetics of disease response to chemotherapy, measured by CT and/or PET scan is used in many cooperative group trials as an important additional tool for the stratification of treatment intensity including the use of radiation (see below).

Treatment and Outcomes. In the 1960s extended-field radiation with doses of 35 to 44 Gy were shown to be curative in a significant portion of patients with Hodgkin

*Adverse disease features (one or more of the following): hilar adenopathy, more than four nodal regions, mediastinal tumor >33% of chest diameter, node or nodal aggregate with diameter >10 cm.

†Presence of one or more of the following: bulky disease, peripheral nodal disease 6 cm or larger, and/or mediastinal tumor one third of intrathoracic diameter or more, and B symptoms.

‡No bulk or extranodal extension.

lymphoma.[141,142] In children, the negative sequelae of high-dose extended-field radiation quickly became apparent.[143] Soon thereafter the MOPP combination was created by Devita and coworkers[20] to treat patients with Hodgkin lymphoma. The basic rationale was to combine single drugs with proven efficacy but different mechanisms of action and resistance that had few overlapping toxicities to maximize antitumor effect and limit side effects caused by use of moderate doses of the individual drugs. The second important combination chemotherapy regimen for the treatment of Hodgkin lymphoma was doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD), which was developed by Bandanna and coworkers.[144] Variations of these two regimens have formed the cornerstone of almost all subsequent chemotherapy regimens.

Combined-modality therapy using both chemotherapy and radiation has emerged as the standard of care for most children and adolescents diagnosed with Hodgkin lymphoma. The use of six cycles of MOPP chemotherapy combined with involved-field radiotherapy (IFRT) was pioneered by the Stanford investigators in children with pathologically staged disease.[145] This pivotal trial has served as the model for combined-modality treatment programs in children.

Subsequent studies evaluated regimens with modifications incorporated designed to minimize risks of late effects while maintaining efficacy. Changes have included both the substitution of drugs the use of which is associated with lower risks of specific long term toxicities as well as limiting the cumulative dose of drugs that are associated with risks of late sequelae in a dose dependent manner. Some modifications have been gender specific. Table 53-5 gives an overview of chemotherapy combinations. With most of these multiagent combinations, comparable high disease-free survival rates have been achieved.[37,38,130,145,146,147]

The balance of efficacy and late risk of the combined-modality of chemotherapy and radiotherapy adopted by the German-Austrian study group has been investigated over a series of trials (Table 53-6). Modifications investigated have included reduction of the cumulative dose of alkylating agents and replacement of mechlorethamine of MOPP with doxorubicin (vincristine [Oncovin], prednisone, procarbazine, and doxorubicin [OPPA]) and cyclophosphamide (cyclophosphamide, vincristine [Oncovin], procarbazine, and prednisone [COPP]); reduction of radiotherapy (volume, dose, and number of patients who receive radiotherapy); and replacement of procarbazine by etoposide for boys. The seventh of the sequential studies built on findings of the previous six trials.[148] In this study the primary aim was to evaluate modifications of therapy to maintain good outcomes for boys but to do so with less gonadotoxic therapy. In this study procarbazine was replaced with higher dose etoposide in the first two cycles and with dacarbazine in the subsequent two to four cycles. The outcomes for boys and girls on this study were superimposable, supporting the efficacy of this regimen.

The second strategy that is of critical importance in trying to maximize efficacy and minimize toxicity is the stratification of treatment intensity based on the patient's risk for relapse. Cooperative group trials of pediatric and adolescent Hodgkin lymphoma have generally divided patients into low-, intermediate-, and high-risk groups (see Table 53-4). In addition to stratification by stage, studies have also evaluated modifications of therapy based on early disease response. Many reports from these therapeutic studies are confined to a distinct risk group of patients. Comparisons among trials confined to patient subsets need to be done with caution, because the risk group definitions vary both based on the patient characteristics at the time of initial staging and the criteria of disease response.

TABLE 53-5 Combination Chemotherapy Courses for Treatment of Hodgkin Lymphoma

Course	Drugs	Dosage and Route	Days
MOPP[21]	Mechlorethamine	6.0 mg/m^2, IV	1, 8
	Vincristine (Oncovin)	1.4 mg/m^2, IV	1, 8

Table 53-7 summarizes treatment strategy and results of therapeutic studies in the patient subgroup defined as low risk. Patients at low risk in general are those with stage I and II disease without B symptoms and without bulky disease. These patients have been shown to have excellent outcomes with sequential trials using two to four cycles of multiagent chemotherapy and low-dose involved-field radiation.[38,145,147] These regimens have been designed to minimize exposure to anthracyclines, alkylators, and epipodophyllotoxins in order to minimize risks of cardiac dysfunction, infertility, and secondary acute myelogenous leukemia (AML), respectively.

Table 53-8 summarizes the treatment strategy and results of selected therapeutic studies in patients considered to have intermediate- or high-risk disease. Chemotherapy for these groups generally consists of combinations of ABVD and MOPP or hybrid regimens. Most regimens contain four to six cycles of chemotherapy followed by involved-field radiation with some including high-dose radiation to bulky or residual sites of disease.

Prognostic information for patients with Hodgkin lymphoma is based on information available at the time of the child's initial evaluation. Additionally the importance of the kinetics of disease response to chemotherapy has been shown to be a predictive factor for this disease, as it has been for pediatric leukemias.[149] The premise is that those with more robust responses to initial chemotherapy have more favorable disease and that responsiveness can be included in the factors that are used to decide the intensity of therapy, including whether irradiation is indicated. The definition of a favorable response to chemotherapy, including the timing of assessment of response, the intensity of the chemotherapy regimen used to get the response, and the tools used to measure response have

[**] CR defined as >70% reduction of initial tumor volume and gallium-negative if initially gallium-positive.

varied widely between study groups and over time. Table 53-9 describes the criteria for disease response evaluations in recent cooperative group trials.

Cross-sectional imaging can define response based on a percentage decrease in size. In Hodgkin lymphoma, a significant proportion of patients have residual masses at the time of disease response assessment and at the end of therapy. Functional imaging methods such as gallium scanning and PET are able to assess metabolically active tissue associated with residual disease (Fig. 53-5). A series of studies primarily performed in adults with Hodgkin lymphoma where therapy was not changed based on interim radiographic results have shown that PET scans performed after two cycles of chemotherapy are highly predictive of outcome.[150-153] The accuracy of PET to predict treatment outcome is higher early in the course of treatment as compared with the end of chemotherapy.[151,154,155] Both the German-Austrian study GPOH-HD2002 and the Children's Oncology Group (COG) studies of intermediate- and high-risk disease addressed the strength of early PET obtained after two cycles of chemotherapy; however the results are still pending.[156]

Several cooperative group studies have focused on modifications of regimens to avoid gender-specific toxicities. The COG evaluated a strategy of stratifying patients with high-risk disease based both on response and gender.[157] All patients received escalated bleomycin, etoposide, doxorubicin (Adriamycin), cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP) therapy for 4 cycles. Patients with a rapid early response, defined as a 70% tumor reduction and having a negative gallium scan after four cycles, were then assigned to subsequent therapy based on gender. Boys received two additional cycles of ABVD designed to minimize risks of infertility and involved field radiation. Girls received four cycles of COPP/doxorubicin (Adriamycin), bleomycin, and vinblastine (ABV) and no radiation in order to avoid the risks of secondary breast cancer. Those with disease that met the criteria for slow early response received an additional 4 cycles of BEACOPP. Seventy-seven percent of girls avoided radiotherapy, whereas 68% of boys avoided alkylating agents during consolidation. The EFS and OS rates remained excellent.

The German GPOH-HD2002 study also evaluated sex-based modifications of therapy but did not use patient response for treatment allocation.[148] Boys received two cycles of dose-intensified vincristine, etoposide, prednisone, and doxorubicin (Adriamycin; OEPA) therapy

[*] CR defined as reduction of tumor volume of >95% and residual mass <2 mL.

[†] Males.

[‡] Females.

[§] Defined as presence of one or more of the following: bulky disease, peripheral nodal disease 6 cm or larger, and/or mediastinal tumor one third of intrathoracic diameter or larger; and B symptoms.

[‖] 15 Gy for nonbulky sites and complete response after two cycles of chemotherapy.

[¶] Bulk defined as mediastinal mass greater than intrathoracic diameter at level of T5 or extrathoracic nodal mass greater than 10cm.

[#] Slow early responders.

[**] SER, partial response not meeting criteria for RER; RER, >70%reduction in tumor volume and gallium negative post 4 cycles.

TABLE 53-9 Definitions of Favorable Response to Therapy in Selected Multicenter Trials in Children and Adolescents with Hodgkin Lymphoma

Study	Definition of Favorable Response	Timing of Assessment	Treatment Modification for Those with Favorable Response
CCG5942[37]	>70% reduction in initial tumor volume and gallium negative	At completion of chemotherapy	Randomized to IFRT or no IFRT
GPOH-HD02[148]	≥95% reduction in tumor volume	After 2, 4, or 6 cycles of chemotherapy depending on disease group	No IFRT for patients with low-stage disease only (TG1)
Stanford-St. Jude-Boston Consortium[609]	≥75% reduction in perpendicular diameters of measurable lesions, or return no normal size and gallium or PET negative	After 2 cycles of VAMP	No IFRT
COG[158]	Disappearance of all clinical and disease-related symptoms and PET negative	After 2 cycles of ABVD-PC	All get IFRT; Less than good response: chemo intensified with additional 2 cycles ifos/vinolebine

ABVD-PC, Doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine–prednisone, cyclophosphamde; *CCG,* Children's Cancer Study Group; *COG,* Children's Oncology Group; *GPOH-HD,* German Society for Pediatric Oncology and Hematology–Hodgkin disease; *IFRT,* involved-field radiotherapy; *PET,* positron emission tomography; *TG1,* therapy group 1; *VAMP,* vinblastine, doxorubicin (Adriamycin), methotrexate, and prednisone.

followed by two (for those with intermediate-risk disease) or four (for those with high-risk disease) cycles of cyclophosphamide, vincristine (Oncovin), prednisone, and dacarbazine (COPDAC) designed to attempt to limit gonadal toxicity. Girls received the same number of cycles but of OPPA followed by COPP. EFS and OS rates did not differ between the two sexes with the regimens employed.

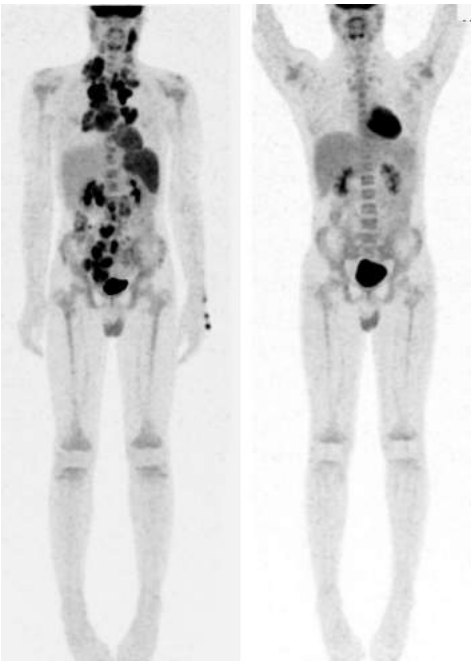

Figure 53-5 PET scan at diagnosis and after two cycles of ABVD-PC chemotherapy in an adolescent with advanced-stage Hodgkin lymphoma.

The Pediatric Oncology Group (POG) evaluated response-based modifications of therapy without modifications for sex in patients with intermediate- and high-risk disease.[158] In this study patients were evaluated for response after three cycles of therapy. Those with a rapid early response defined as a greater-than-70% reduction in disease and gallium negative, received 21 Gy IFRT. Those who were slow responders received an additional two cycles followed by radiation. With this strategy the 5-year EFS rate was the same in both groups, and the OS rate was 95%.

Whether radiotherapy can be omitted from treatment for at least some children and adolescents with Hodgkin lymphoma is one of the important questions in recent and ongoing clinical trials. Three cooperative group trials in the low-risk group each evaluated the removal of IFRT in a subset of patients with largely successful results. In the Stanford-St.Jude-Boston protocol, patients with a complete response, defined as greater than 75% reduction of the sum of the perpendicular of all lesions after two cycles of vinblastine, doxorubicin (Adriamycin), methotrexate (methotrexate), and prednisone (VAMP) chemotherapy were nonrandomly assigned to no radiation. All patients received four cycles of VAMP chemotherapy. Fifty three percent of patients met criteria for complete response. The 2-year EFS rates of this group were no different from those who did receive radiation, at 89% and 92% respectively.[159] The GPOH-HD 2002 study also nonrandomly assigned patients at low risk with a complete response after two cycles, defined as more than 95% volume reduction, to no radiation. Thirty three percent of patients met this criterion, did not receive radiation, and had an outcome identical to those who did receive IFRT, with EFS rates at 5 years of 93% and 91% respectively.[148] The Children's Cancer Group (CCG) study 5942 randomly assigned patients who obtained a complete remission (CR), defined as 70% mass reduction

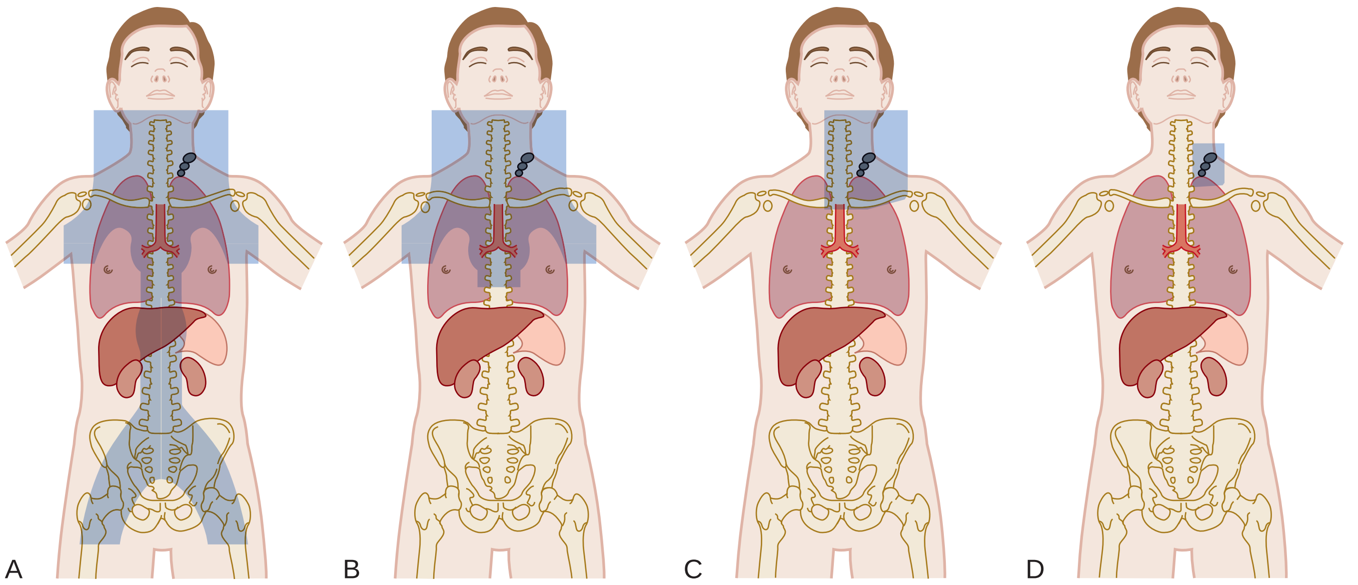

Figure 53-6 Radiation fields for treating Hodgkin lymphoma. **A,** Total nodal irradiation. **B,** Mantle field. **C,** Involved field. **D,** Radiation field individualized to the patient's local disease, taking into account the tolerance of involved or adjacent extranodal organs. *(Courtesy of Dr. W. Dörffel, Berlin, Germany.)*

of tumor volume and negative gallium scan, to radiation or no radiation after four cycles of COPP/ABV therapy. The EFS rates for randomized patients at 3 years were significantly different at 97% versus 91%; however, the OS rate at 3 years in both groups was 100%.[37]

Omission of radiation has also been investigated in subgroups of patients with intermediate- and high-risk disease with mixed results. In the POG trial 8725, patients with stages IIB, IIIA2, IIIB, and IV were randomized to receive eight alternating cycles of MOPP/ABVD chemotherapy followed by total nodal irradiation (21 Gy) or no radiotherapy in cases of CR.[160] There was no difference in EFS or OS between patient groups who did or did not receive radiation. In the GPOH-HD95 trial patients who achieved a complete response received no further therapy, whereas those who did not received 20 to 35 Gy of IFRT.[38] In the intermediate- and high-risk groups, omission of radiation was associated with a significantly decreased EFS rate of 77% for those treated with chemotherapy only versus 92% for those who received combined modality therapy.

The CCG5942 trial included subjects with all disease stages. Based on their risk-group assignment, patients received either four or six cycles of COPP/ABV or six cycles of the mutiagent ABC regimen chemotherapy.[37] Patients with at least a 70% tumor-volume reduction and negative gallium scan at the completion of chemotherapy were randomized to receive or not receive IFRT with 21 Gy. This randomized trial was stopped because of a significantly higher number of relapses in the no-IFRT arm. Most of the relapses were at sites of initial disease. Patients who did not receive IFRT had an EFS rate at 3 years from the time of randomization of 87% compared with 92% ($P = .057$) for patients treated with IFRT in the intent-to-treat analysis. Importantly, longer term follow-up study of this cohort has shown that the OS in the two arms is no different. At 10 years postrandomization, the EFS of those treated or not treated with IFRT were 91.2% and 82.9% ($P = .004$), respectively, whereas the OS of the two groups were 97.2% and 95.5% ($P = .5$), respectively.[161]

Radiation remains a critical component of therapy for the majority of children and adolescents with Hodgkin lymphoma. Radiotherapy planning involves decision making about both dosage and field, with the goals of maximizing efficacy but limiting late effects. Radiation fields have evolved over time (Fig. 53-6). IFRT, used in the majority of contemporary protocols, generally involves radiation of the entire lymph-node region that includes the pathologically enlarged node.[23] One major implication of the change from mantle-field radiation to IFRT for cervical disease is the exclusion of the axilla, which significantly reduces the exposure of lung and breast tissue. Investigations of further limitations to radiation fields are ongoing. The dosages in most contemporary studies used in combination with chemotherapy are generally no greater than 21 Gy, with some studies using higher dosages to sites of bulky or residual disease.

Disease Surveillance after Completion of Therapy

Driven both by required studies as part of clinical trials and as part of standard of care in some pediatric oncology settings, children and adolescents routinely undergo surveillance imaging with CT scans at regular intervals after completion of therapy. Given increasing awareness of the potential risks secondary to imaging-related radiation exposure, recent work has examined the utility of CT imaging as compared with clinical findings in the detection of disease recurrence.[162] A retrospective review of patients treated in a POG study showed that the majority of relapses occurred within the first year and were detected by clinical findings. For the patients with late relapse, detection by either by clinical symptoms or surveillance imaging did not change the OS rate.[163] These authors suggest limiting surveillance-CT imaging to the first 12 months after completion of therapy. FDG-PET scanning, which has utility in staging newly diagnosed patients and in the assessment of disease response (see above) has no established role in off-therapy surveillance.[164] More widespread use of MRI as a replacement for CT may also allow for reduction of radiation exposure in lymphoma patients in the future.[165]

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Pathologic Features

NLPHL is a monoclonal B-cell neoplasm.[35,166] The histology is characterized by effacement of the lymph node architecture by a nodular or nodular and diffuse infiltrate of small lymphocytes, with an associated follicular dendritic network and scattered or clustered large cells referred to as *lymphocytic and histiocytic (L&H) cells*.[26,35] NLPHL corresponds to Hodgkin paragranuloma of the classification of Jackson and Parker from 1947[167] and to lymphocyte-predominant Hodgkin lymphoma of the Rye modification of Lukes and Butler.[24] Differentiation of NLPHL from the lymphocyte-rich subtype of classic Hodgkin lymphoma can be difficult in some cases. However, the phenotype of L&H cells (also termed *popcorn cells* because of their often multilobed nuclei) is different than classic Reed-Sternberg cells of the CHL subtypes in that they express CD45 and usually retain most normal markers of B-cell differentiation, such as CD20, CD79a, and the B-cell specific transcription factors BOB.1 and Oct-2, but do not express CD30 and CD15 (see Table 53-1).[26,35] Also, markers of EBV infection are consistently absent from L&H cells of NLPLH.[166] In some patients with NLPHL, progressively transformed germinal centers are observed in association with NPLHL. However, it remains uncertain whether these lesions are truly preneoplastic, because most patients with such lesions in reactive lymph-node hyperplasia do not develop a lymphoma.[168]

Clinical Features

NLPHL comprises between 5% and 8% of Hodgkin lymphoma in children and adolescents and accounts for an even higher percentage of prepubertal patients.[169] Unlike in patients with CHL, there is a significant male preponderance in those with NLPHL. The disease course is more indolent, and a higher proportion of patients have low-stage disease, most often presenting as localized peripheral adenopathy, most commonly in the neck and less commonly in the inguinal area. Mediastinal involvement is relatively rare.[170] Unlike CHL, where contiguous nodal spread is the norm, in NLPHD noncontiguous spread is observed in those with high-stage disease. The pattern of relapse of disease also differs from CHL, with relapses occurring late and often repeatedly.[171,172] An additional unique feature of NLPHL is the increased risk of transformation to NHL occurring in 5% to 12% of cases, whereas this is very rarely observed in CHD.[173]

Diagnostic evaluation should include excisional node biopsy. Fine-needle aspirate is often inadequate and can lead to the misdiagnosis of reactive nodal tissue.[174] Staging of patients with NLPHL uses the Ann Arbor system as used for CHL, and staging evaluations to be considered are the same as those for a patient with CHL except that bone marrow biopsies are rarely indicated. The only consistent prognostic factor for patients with NLPHL is stage of disease, although some data suggest that a ratio of lymphocyte count to monocyte count at the time of diagnosis may also have prognostic value.[175,176]

Treatment and Outcomes

Historically patients with NLPHL have been included in most therapeutic studies of childhood and adolescent Hodgkin lymphoma. Uncertainty remains about optimal therapy for these patients. Given the favorable prognosis and the burden of late effects from therapy, the evaluation of less intensive regimens has been undertaken.[177]

The majority of patients with NLPHL have low-stage disease, which is sometimes amenable to complete resection. One of the unique features of NLPHD is that a portion of children with low-stage disease treated with resection alone are cured of their disease. Studies of patients treated in this fashion have reported relapse-free survival rates of 67% to 100%.[178-181] All of the recurrences in patients with relapse were low stage, and the OS has been reported as 100%.[180] For pediatric patients with NLPHD, a watchful waiting approach for those who are in CR after initial surgery is appropriate. However, a careful postoperative staging and meticulous follow-up observation is essential. Other strategies for patients with low-stage disease are the use of radiotherapy alone[175] or low-intensity alkylator-based chemotherapy regimens.[182,183]

Data to evaluate the best therapy for patients with advanced stage NLPHL are relatively scarce. Outcome of these patients is similar to those with CHL, and the usual recommendation is that they receive therapy similar to those with advanced-stage CHL. Investigation of the possible role for therapy with rituximab as a single agent or as part of combination therapy for this disease are ongoing.

Treatment of Relapsed Hodgkin Lymphoma

Although the success of primary therapy for children and adolescents is high, approximately 10% of patients develop relapsed disease.[184] The outcome for those with relapsed disease is variable. The two strongest predictive factors are time to relapse and response to reinduction chemotherapy.[185-187] Time to relapse can be subdivided into three prognostic groups: 1) patients with primary refractory disease or recurrent disease within the first 3 months have the worst outcomes; 2) those with disease relapse within 12 months of diagnosis form an intermediate group; and 3) those with relapses occurring longer than 12 months from diagnosis have the most favorable outcome.[188] Patients who have no response to reinduction therapy have a dismal prognosis, as do those with active disease immediately before autologous stem cell transplantation (SCT).[189,190] Additional prognostic factors include the intensity of primary therapy, stage, and B symptoms at relapse.

There is no consensus on optimal salvage therapy for children with relapsed disease. The options include chemotherapy with or without radiation, autologous SCT, allogeneic SCT, or novel therapies. Data to support treatment choices can be difficult to interpret because there is a lack of randomized trials evaluating these therapeutic options in children; the majority of studies in patients with relapse have been single-arm trials with varying inclusion criteria.

Patients with late relapse who have responsive disease to reinduction therapy have a favorable prognosis with treatment with chemotherapy and radiation.[188] Chemotherapy regimens have been evaluated in this setting including ifosfamide, carboplatin, and etoposide (ICE)[188]; carmustine (BCNU), etoposide, cytarabine (ara-C), and melphalan (miniBEAM)[191]; cytarabine, cisplatinum, and etoposide (APE)[192]; as well as newer regimens including gemcitabine and vinorelbine (GV)[193] among others. Information that should be considered in choosing a salvage regimen should include knowledge of the frontline therapy used, in part to avoid toxicities with cumulative drug exposure.

For patients with high-risk relapsed disease, intensifying therapy with autologous SCT should be considered, although controversy about which patients are likely to benefit from this therapy remains. In a prospective randomized trial of the German Hodgkin Lymphoma Study Group, adults with chemotherapy-sensitive disease had a significantly higher failure-free survival probability when treated with two cycles of dexamethasone, carmustine (BCNU), etoposide, cytarabine (ara-C), and melphalan (Dexa-BEAM) followed by autologous SCT compared with patients receiving four cycles of Dexa-BEAM without SCT.[194] For childhood Hodgkin lymphoma there are very few prospective or randomized trials. In a retrospective study of 51 pediatric patients with recurrent Hodgkin lymphoma treated with different salvage regimens, there was a beneficial impact of autologous SCT on survival only for patients refractory to first-line therapy, but sensitive to second-line therapy disease.[195] The outcome of children with disease that is unresponsive to chemotherapy who undergo autologous SCT is dismal.[184]

The European trial for children with relapsed Hodgkin lymphoma, EuroNet-PHL-C1, divides patients into low-, intermediate- and high-risk groups based on time to relapse and early response assessment. Patients with low-risk disease are treated with chemotherapy and radiation. Those with high-risk disease have their therapy intensified with autologous SCT. Those with intermediate-risk disease have therapy allocated based on response, with those with a good response receiving chemotherapy and radiotherapy only.

The use of allogeneic transplant in relapsed Hodgkin lymphoma, with the hopes of making use of graft-versus-lymphoma effects has been investigated including myeloablative SCT, reduced intensity SCT, and reduced intensity SCT after autologous SCT.[196,197] In this very–high-risk group, both relapsed disease and transplant-related mortality limit the adoption of this therapy except for those patients with adequate performance status and limited curative options.[184]

Novel therapies for relapsed disease are needed. One agent that shows significant promise is the antibody-drug conjugate brentuximab vedotin (also known as *SGN-35*), which combines an anti-CD30 monoclonal antibody with the antimicrotubule agent, monomethyl auristatin E. In a phase 2 study of patients with very–high-risk disease (71% had primary refractory disease, and 100% of patients had previously been treated with autologous SCT), the overall response rate was 75%, with 34% of patients achieving a CR and with a high percentage of these patients remaining without evidence of relapsed disease at 1.5 years. The median age of the patients in this trial was 31 years, with the youngest being 15 years old. Toxicity of the agent was relatively mild, including neuropathy and cytopenias.[198] The safety and effectiveness of adding this agent to standard chemotherapy as well as including it in front-line therapy is being investigated by several cooperative groups.

Late Effects of Therapy

Given the high rate of cure in children and adolescents with Hodgkin lymphoma, the risks of long-term effects of treatment are very important. In the scientific literature, the number of reports on late sequelae after successful treatment of pediatric Hodgkin lymphoma patients has exceeded that of reports on prospective therapeutic trials. Many of these reports document late sequelae associated with earlier treatment approaches. The treatment for pediatric Hodgkin lymphoma has evolved because of a continuous process of attempting to maximize efficacy while limiting the long-term risks of therapy. Therefore many of the reports of sequelae of therapy administered several decades ago may not accurately reflect the risks of late effects associated with current treatment strategies.

Some late effects of Hodgkin lymphoma therapy can be attributed to a distinct treatment modality or a single drug; others may have a multifactorial pathogenesis. Table 53-10 lists late effects that have impact on morbidity and mortality, as well as those that affect the quality of life for survivors.

In two large, single-center series of patients with pediatric Hodgkin lymphoma treated over several decades, the long-term cumulative risk of death from treatment-related sequelae such as infections, cardiac disease, and second cancers approached that of the risk of death from relapsed Hodgkin lymphoma.[199,200] Data from 2742 patients treated between 1970 and 1986 who were under the age of 21 at the time of diagnosis, who were alive longer than 5 years posttherapy, and who were in the Childhood Cancer Survivor Study (CCSS) has delineated the risks and causes of excess mortality.[201] With a median follow-up length of greater than 20 years, of the 500 observed deaths in the cohort, 35% were from Hodgkin lymphoma, 23% from second malignant neoplasms (SMNs), and 14% from cardiovascular disease. The 30-year OS rate from diagnosis was 74%.

SMNs are devastating sequelae of therapy for Hodgkin lymphoma. In the U.S. Childhood Cancer Survivor

TABLE 53-10 Late Effects of Treatment of Children and Adolescents with Hodgkin Lymphoma

Late Effect	Radiotherapy	Chemotherapy
Musculoskeletal growth impairment[201]	X

Solid tumors[202-213]	X	

BCNU, Carmustine; *CCNU,* lomustine.

Cohort consisting of more than 13,000 survivors of childhood cancers, patients treated for Hodgkin lymphoma were at the highest risk to develop an SMN.[202] Patients treated with full-dose radiation are at significant risk for SMNs with a cumulative incidence of greater than 25% after 30 years of follow-up study.[203,204] Fifteen years postdiagnosis of Hodgkin lymphoma, the second leading cause of mortality after death from the primary disease is death from an SMN.[205] Breast cancer makes up the largest component of the excess solid tumors in female patients.[203]

Contemporary therapy no longer uses high-dose extended-field radiation. The impact of lowering radiation dosage and the use of combination chemotherapy on risks of SMN continues to be investigated. In a cohort study including both children and adults treated for Hodgkin lymphoma, 459 second malignancies were described in 5798 patients.[206] These patients were treated between 1963 and 2001. All received chemotherapy, and 3432 also received radiation. Of those who received chemotherapy only, there remained significantly increased risks of second malignancies including leukemia, NHL, and lung cancer with the peak period of risk between 5 and 9 years posttherapy. For those who received combined modality therapy including radiation, the absolute risk of an SMN was significantly higher and included a wider arrays of malignancies; the period of risk extended to 25 years and longer. In a small cohort of 112 pediatric patients treated at a single institution between 1970 and 1990 with combined modality therapy including 15 to 25.5 Gy IFRT, the rate of SMN including sarcomas and breast and thyroid carcinomas was similar to that reported in studies of patients who had received higher doses of radiation.[207] Other studies have suggested that low-dose radiation and limiting cumulative alkylator exposure may have a protective effect in adult patients but not in children.[208] Still others have shown that patients who received less than 23 Gy of mediastinal radiation had a lower incidence of breast cancer, which may in part be related to the transition from extended-field radiation to IFRT.[209] The cumulative incidence of second leukemias ranges from 0.6% to 2.1% and reaches a plateau after 10 to 14 years.[131,200,204,210,211] The risk of second leukemias is associated with the cumulative dose of alkylating agents and is almost absent in patients treated with radiotherapy alone.[200,204] The risk of developing thyroid cancer is clearly related to radiotherapy and is highest in young children.[203,204,212] Almost all thyroid tumors arise within the radiation field.[204] A recent study analyzing the genetic factors that may contribute to radiation-induced tumors in survivors of Hodgkin lymphoma has identified variants at chromosome band 6q21, implicating the *PRDM1* gene in the etiology of secondary malignancies.[213]

Cardiovascular disease contributes significantly to the morbidity and mortality of patients who are survivors of Hodgkin lymphoma.[201] Damage to the heart after full dose radiotherapy includes coronary artery disease, valvular pathology, and pericardial disease.[214] Cardiomyopathy with ventricular dysfunction can result from anthracycline therapy.[215] Risks of late anthracycline cardiotoxicity are higher in young children, in girls, and with higher cumulative doses.[216,217] In long-term follow-up observation of a cohort of patients from a single-center combination of exposure to mediastinal radiation and anthracycline was associated with the highest risk of cardiac morbidity.[218] Data regarding the long-term cardiac risks associated with contemporary therapy using low-dose IFRT and chemotherapy regimens that generally limit cumulative anthracyclines exposure to less than 250 mg/m^2 are needed.

Death from overwhelming infections related to splenectomy was a major risk that has been significantly reduced since splenectomy was abandoned from staging procedures.[131,199] Irradiation of the spleen may also induce functional impairment of the spleen, at least if dosages of 20 Gy or more are used.[219]

Chronic lung disease can result from irradiation of the lung and exposure to several chemotherapy agents used in Hodgkin lymphoma regimens, including bleomycin and the nitrosourea derivatives BCNU and lomustine (CCNU). The cumulative dose of these drugs is the most crucial determinant for chronic lung injury. Very young age may be an additional risk factor for possible fatal lung toxicity from BCNU and CCNU.[220] The combination of radiotherapy and drugs with lung toxicity contributes to increased risk of long-term lung impairments. This is of special concern in patients requiring salvage treatment for recurrent Hodgkin lymphoma that includes high-dose chemotherapy.

Survivors of pediatric Hodgkin lymphoma are at increased risk for thyroid malfunction—mainly hypothyroidism but also hyperthyroidism, benign and malignant thyroid nodules, and Graves disease.[221] The risk increases with the dose of neck irradiation, younger age at treatment, and female gender.[222]

Musculoskeletal growth impairment was one of the first sequelae recognized to be a consequence of high-dose radiotherapy for children with Hodgkin lymphoma.[143] Prepubertal children treated with 40 Gy of mantle irradiation would have predictable sequelae of lack of growth of the bone and soft tissues of the neck and clavicles, leading to orthopedic complications as well as significant cosmetic effects. This complication is ameliorated by low-dose IFRT used in most contemporary regimens.

The primary risk factor for gonadal toxicity is exposure to alkylating agents, primarily cyclophosphamide and procarbazine.[223,224] Historically mechlorethamine was the primary cause of chemotherapy-related sterility in males. Dose-dependent testicular damage from germ-cell depletion and Leydig-cell dysfunction has also been documented in prepubertal and postpubertal boys after MOPP; chlorambucil, vinblastine, procarbazine and prednisone (ChlVPP); and OPPA-COPP chemotherapy.[225,226] The ABVD regimen appears to be less toxic to germ cells.[227] Results from the German-Austrian studies on pediatric Hodgkin lymphoma have shown clearly that with moderate doses of cyclophosphamide, male infertility correlates with the cumulative dose of procarbazine. Historically in girls, the most substantial risk of infertility was from pelvic lymph node irradiation and was ameliorated to some extent by ovarian transposition.[143,228] The risks of early menopause for females receiving contemporary therapy is likely fairly low, and small studies have shown no measurable impact of ABVD therapy on fertility in women.[229]

Follow-up care of survivors of Hodgkin lymphoma should follow a structured plan such as that described in the *COG Long-Term Follow-up Guidelines*.[230,231] Availability of a detailed and accurate treatment summary is imperative to determining appropriate care and surveillance investigations in follow-up observation.

NON-HODGKIN LYMPHOMA

NHLs are a diverse collection of malignant neoplasms of lymphoid cell origin, including all the malignant lymphomas that are not classified as Hodgkin lymphoma. They account for 7% of all cancers in those younger than 20 years old.[232] NHLs are heterogeneous in their pathology, clinical features, and responsiveness to therapy. With improved understanding of biology and data from sequential disease-based clinical trials as well as better supportive care, the outcome of children with NHL has improved dramatically over the last several decades. With conventional therapy, depending on subtype and stage, the majority of children with NHL can be cured of their disease.

The classification of NHL has been and continues to be a topic of scientific discussion and a source of confusion for clinicians. The Rappaport system used growth patterns (diffuse vs. nodular) and cytology (undifferentiated vs. differentiated) as the basic criteria for disease definitions.[233] The Lukes Collins classification system was based primarily on splitting the lymphocytic system into T and B lymphocytes.[234] The Kiel classification system attempted to translate information about how the lymphatic system is organized into a classification system for NHL, in which the lymphoma cells were related morphologically and immunophenotypically to the normal cell categories of the immune system.[235,236] The National Cancer Institute Working Formulation for Clinical Usage, established in 1982, did not intend to constitute another classification of NHL; rather it was to be a common language to translate between existing classifications.[237] It took into consideration the clinical course of patients and resulted in a grading of NHL into low-grade, intermediate-grade, and high-grade NHL. This system was widely used by clinicians in North America. In Europe and Asia, the Kiel classification was more broadly used. The use of different classification systems hampered or even made it impossible to compare results of clinical trials. In the 1990s, the International Lymphoma Study Group undertook a major effort to overcome this confusion and to create a uniform classification of NHL based on biologic principles. The result was the Revised European-American Classification of Lymphoid Neoplasms (REAL) classification, which then lead to the WHO Classification of Tumors of the Hematopoietic and Lymphoid Tissues produced in 2002 and revised in 2008.[25] The basic principles of the WHO classification system include subdivision of neoplasms according to the lineage (B, T, or natural killer [NK] cell) and the definition of distinct subtypes within each lineage according to a combination of morphology, immunophenotype, genetic features, and clinical features.

The revisions of the WHO classification system in 2008 included diseases that overlap between entities, such as B-cell lymphomas with features intermediate between DLBCL and BL and B-cell lymphomas with features intermediate between DLBCL and Hodgkin lymphoma. In addition, age-specific factors defined several new disorders including pediatric type follicular lymphoma (FL) and systemic EBV-positive T-cell lymphoproliferative disease of childhood.[238]

Combination chemotherapy is the cornerstone of successful treatment of children and adolescents with NHL. A key moment in the development of current treatment concepts was the recognition that different NHL subtypes require different chemotherapeutic strategies. In children and adolescents with NHL, three main disease groups account for the vast majority of the diagnoses. The three are LL, mature B-cell neoplasms (including BL and DLBCL), and anaplastic large-cell lymphoma (ALCL; Fig. 53-7). In the era of solid organ and SCT, posttransplant lymphoproliferative diseases are becoming more common.

Epidemiology and Causative Factors

There is significant variation in incidence rates according to geographic areas, gender, age, and ethnicity in

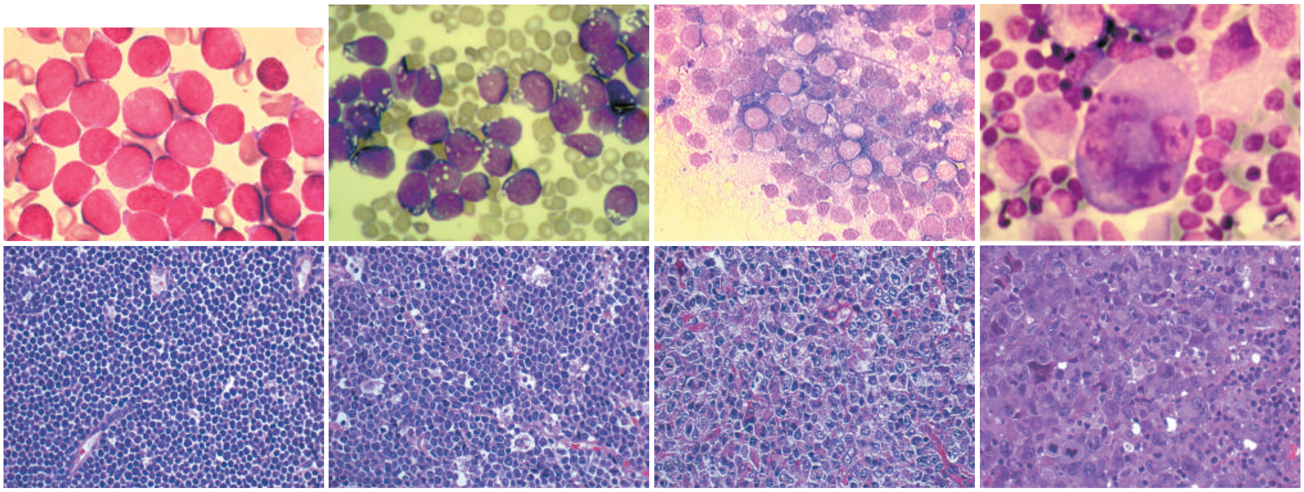

Figure 53-7 Morphology, immunophenotype, and specific cytogenetics of main non-Hodgkin lymphoma subtypes of childhood and adolescence.

childhood NHL. The comparison of incidence rates of NHL in childhood and adolescence in different geographic areas is limited because of a paucity of true population-based registries, different degrees of completeness of data, and the use of various disease classification systems over time. The reported incidence rates range from 6.6 per million population in the United Kingdom to 12.5 per million in Japan. Specific subtypes of NHL, however, occur at a much higher rate in particular regions. Endemic BL accounts for 74% of all childhood malignancies in equatorial Africa, whereas all NHLs combined account for 7% of pediatric cancer in North America.[239-241]

In all registries the incidence rates of NHL are higher in males than in females, usually by a factor of 2.[242-246] The male-to-female ratio varies considerably among different NHL subtypes. Whether male predominance in most NHL subtypes reflects hormonal differences rather than loss of an X-chromosome–linked tumor suppressor gene remains to be determined. The incidence of NHL and of the various subtypes varies widely by age, with substantial differences between children and adults. Among patients younger than 18 years of age there is also considerable variability (Fig. 53-8).[247] NHL as a whole in children younger than 3 years of age is extremely rare. BL or leukemia is the predominant subtype in younger children. The incidence of DLBCL and ALCL increases in those older than 15 years of age.

In the U.S. Surveillance, Epidemiology, and End Results (SEER) program, the incidence rate in Caucasian children is higher as compared with African American children.[242,248] In adults, an increased risk for NHL has been described in first-degree relatives of patients with hematopoietic malignancies.[101,249] Except for classic known hereditary immunodeficiency syndromes predisposing for NHL, only a few specific genes have been associated with risks of childhood NHL. Biallelic mutations in mismatch repair genes have been associated in a series of families

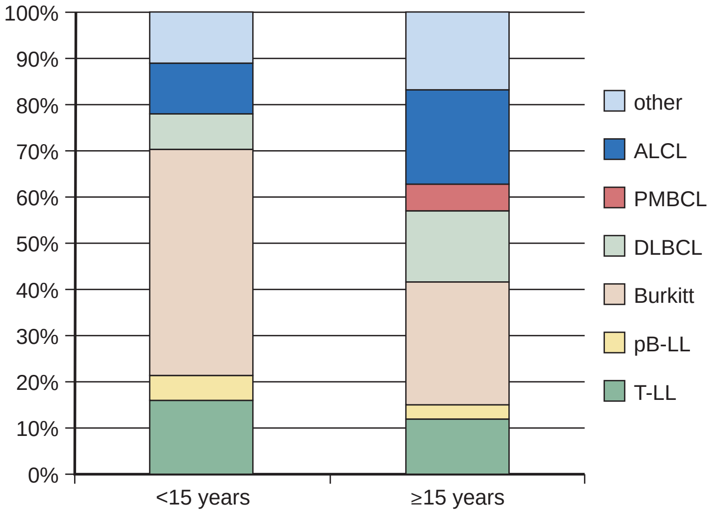

Figure 53-8 Distribution of non-Hodgkin lymphoma subtypes by age. *(Modified from Burkhardt B, Oschlies I, Klapper W et al: Non-Hodgkin's lymphoma in adolescents: experiences in experiences in 378 adolescent NHL patients treated according to pediatric NHL-BFM protocols.* Leukemia *25:153–60, 2011.)*

with several types of childhood malignancies including T-cell lymphomas.[250]

Conclusive data to support the association of environmental factors and risk of childhood NHL are extremely limited. Conversely, data to support the role of infection in a subset of NHLs has been long established. Denis Burkitt not only recognized and described BL as a new disease entity but also established the epidemiologic basics for the current view of its association with EBV, malaria, and possibly arbovirus infections and described the lymphoma belt of Africa."[240,251] In 1964, Epstein and associates[252] described viral particles—later referred to as EBV—in BL samples from African patients. Subsequently the EBV genome was found to be incorporated into 96% of endemic BL cases in the African lymphoma belt, whereas in France and Germany, only 10% to 15% of cases are EBV-positive.[253] It was postulated that EBV infection in addition to exposure to malaria and possibly arboviral infections early in life may be crucial for the pathogenesis of endemic EBV-positive BL.[240,241,254-256] In addition to endemic BL, lymphoproliferative disease, and lymphomas in children with acquired or congenital immunodeficiency are often EBV positive.

Inherited and acquired immunodeficiency is a strong risk factor for developing NHL during childhood.[257] Table 53-11 presents the most common inherited immunodeficiencies associated with lymphoproliferative disorders and lymphoma.[258] For patients with these inherited (also called *primary*) immunodeficiencies, the chance of dying of lymphoma is 10 to 200 times the expected rate for age-matched unaffected children. Many of the lymphomas in this patient group are EBV-positive. There is a male preponderance, partly explained by the fact that some of the inherited immunodeficiencies are X-linked disorders.[259] Children infected with human immunodeficiency virus (HIV) have more than 150 times the risk of developing NHL in comparison with general population rates.[260,261] NHLs are the most common neoplasms occurring in children with HIV, and most are of B-cell lineage.[262,263] For some children NHL may be the first defining condition for acquired immunodeficiency syndrome (AIDS).[262,263] The introduction of highly active antiretroviral therapy has been associated with a significant decrease the incidence of some HIV-related malignancies, such as Kaposi sarcoma, but the effect on the incidence of NHL appears to be more modest.[264]

Initial Evaluation and Staging

As is the case for patients with HL, the most common symptom of childhood NHL is painless lymphadenopathy. In contrast to Hodgkin lymphoma, the nodes may enlarge more rapidly because of a much higher growth fraction of NHL. The variety of presenting features of childhood NHL is even larger than that for Hodgkin lymphoma, ranging from a single painless enlarged lymph node, an asymptomatic asymmetrical enlarged tonsil, or a harmless-looking skin papule to a life-threatening condition. Almost any organ, tissue, and anatomic area can be involved. The most common disease sites are the cervical lymph nodes, abdomen (including the liver and spleen), mediastinum, and head and neck region. Lesions in the head and neck area may involve the tonsils, Waldeyer ring, paranasal sinuses, and any bone structure

TABLE 53-11 Inherited Immunodeficiency Syndromes Associated with Lymphoma in Children

Syndrome	Genetics/Pathogenesis	Immune Defect	Malignancy
Ataxia telangiectasia	*ATM*; impaired DNA repair	Progressive decline in T cells, abnormal immunoglobulins	T-cell ALL and T-cell LL, CHL, BL, DLBCL
Wiskott-Aldrich syndrome (WAS)	*WASP*; abnormal cytoskeletal architecture of hematopoietic cells	Defects in T cells, B cells, neutrophils, macrophages	EBV-associated DLBCL, Hodgkin, lymphomatoid granulomatosis
Severe combined immunodeficiency (SCID)	X-linked: gamma chain mutations with defective IL signaling; *ADA*: defective adenosine deaminase	Dependent of subtype but in general low or absent T and NK cells, nonfunctional B cells	EBV-associated lesions
X-linked lymphoproliferative disease (XLP)	*SH2D1A*; *SAP*, which modulates B- and T-cell interactions	Defective EBV-specific T and NK cells	EBV-associated hematophagocytic lymphohistiocytosis, B-cell lymphoproliferative disease
Autoimmune lymphoproliferative syndrome (ALPS)	Defects in *FAS*-mediated apoptosis pathway	Increased CD4 and CD8 T cells	LPHL, CHL, DLBCL, BL
Common variable immunodeficiency (CVID)	Defects in genes encoding *ICOS*, CD19, *BAFFR*	Low IgG and IgA, decreased B cells	EBV-associated lesions, DLBCL, Hodgkin
X-linked hyperimmunoglobulin M syndrome	CD40 ligand mutation leading to defective B cells	Low or absent IgG and IgA, variable T-cell defects	EBV-associated lesions, DLBCL, Hodgkin

Modified from Tran H: Immunodeficiency associated lymphomas, Blood Rev *22:261–281, 2008.*

ALL, Acute lymphoblastic leukemia; *BL,* Burkitt lymphoma; *CHL,* classic Hodgkin lymphoma; *DLBCL,* diffuse large B-cell lymphoma; *DNA,* deoxyribonucleic acid; *EBV,* Epstein-Barr virus; *Ig,* immunoglobulin; *IL,* interleukin; *LL,* lymphoblastic lymphoma; *LPHL,* lymphocyte-predominant Hodgkin lymphoma; *NK,* natural killer.

including the skull and cranial base. Other sites are bone, soft tissue, kidneys, and skin. Testicular involvement occurs in fewer than 5% of boys and usually manifests as painless unilateral or bilateral enlargement of the testicle. Involvement of ovaries is diagnosed in fewer than 5% of females. The pancreas, adrenal glands, thyroid gland, and salivary glands are rarely affected.

The presenting clinical features, largely based on the site of disease leading to symptoms, vary considerably between different NHL subtypes. Because of the variety of clinical patterns of sites in childhood NHL, careful history and physical examination is essential and should focus on signs and symptoms associated with possible emergent problems such as respiratory compromise from a mediastinal mass or bowel obstruction from abdominal disease. Because CNS involvement is not uncommon in B-cell NHL and LL, careful neurologic examination is necessary to detect signs of cranial nerve involvement, paresis, or increased intracranial pressure. Special attention should be directed to the examination of the skin because of the relatively common involvement, especially in patients with ALCL.

Basic laboratory studies include peripheral blood counts, serum concentrations of LDH, basic coagulation parameters, liver and renal function tests, and serum electrolyte levels. Chest x-ray is critical before anesthesia for invasive procedures to evaluate for mediastinal disease. Other imaging studies vary based on clinical presentation and pathologic information but almost always include CT of the chest. Imaging of the abdomen can be done by CT, although in some centers this is done by ultrasound or MRI. Cranial and spinal imaging is mandatory in any patient for whom there are concerns of possible neurologic impairment. Determination of sites of metastatic disease, except for bone marrow and cerebrospinal fluid (CSF), is largely based on clinical and imaging findings. The use of additional biopsy for staging purposes should be restricted to cases where the findings are uncertain and involvement or noninvolvement would alter treatment.

The involvement of bone marrow and the CNS affects treatment of all subtypes of childhood NHL and therefore needs special attention. Historically, bone-marrow involvement was diagnosed if more than 5% blasts are present in a representative bone-marrow aspiration smear detectable by morphology alone. With the use of flow cytometry and polymerase chain reaction (PCR) for detection of disease-specific genetic alterations, smaller percentages of disease cells in the bone marrow can be routinely detected. A generally agreed upon convention regarding the threshold of detection for allocation of patients as bone marrow-positive or not is lacking. With modern immunophenotyping techniques the additive value of bone-marrow biopsies is somewhat unclear.

There is no internationally standardized definition of CNS involvement in childhood NHL. The definition of CNS involvement includes those patients with an intracerebral mass and/or lymphoma cells in the CSF.[265-269] Opinions differ on how patients with cranial nerve paralysis and paraspinal involvement should be classified, and these patients have been allocated to both CNS-positive and CNS-negative groups in different cooperative group studies.

Despite its increasing use, the role of FDG-PET in the initial evaluation and staging of children with NHL is unclear. FDG-PET is highly sensitive and specific for the detection of sites of disease involvement.[270,271] In adult patients there is evidence of clinical benefit for the use of FDG-PET in disease-response assessment for those patients with Hodgkin lymphoma and DLBCL; however its use for initial staging and for disease response assessment in those with other histologies is less clear.[272] As is true with the introduction of any new, more sensitive testing modality, the risk of its use is "upstaging" patients with the consequence of them receiving potentially unnecessary intensive therapy. Prospective studies are required to evaluate and verify the diagnostic role of FDG-PET in staging and to assess whether the findings of FDG-PET compared with conventional imaging translate into different staging, and more importantly, whether this affects patients' outcomes. The use of FDG-PET as a tool for evaluation of the kinetics of response to therapy as a prognostic marker in children with NHL also requires careful investigation. For this indication, pretreatment FDG-PET is indicated, at least for distinct NHL subtypes with variable FDG uptake.[126]

Skeletal scintigraphy (either FDG-PET or bone scan) can detect bone involvement. Skeletal involvement was not found to be a prognostic factor in several analyses, and therefore bone imaging with skeletal scintigraphy to detect clinically occult bone foci is unnecessary.[273-276] Specific imaging procedures may be indicated in patients with symptoms of bone involvement such as pain and swelling. Larger bone lesions are almost always symptomatic and can be imaged using simple x-ray and evaluated further with MRI if needed.

Obtaining tissue for accurate disease diagnosis is critical. If a malignant lymphoma is suspected, it is important to determine whether the diagnosis can be confirmed with minimally invasive tests. Many children have advanced-stage disease at diagnosis, including bone marrow disease and/or malignant effusions. In many of these cases, correct diagnosis can be made by cytology, immunophenotyping by flow cytometry, and genetic evaluation of bone marrow or effusion samples. A diagnostic surgical procedure should be performed if a definitive diagnosis cannot be achieved by less invasive means. If surgery is to be performed, the procedure should be minimally invasive and should only be used to provide enough biopsy material to characterize the disease fully. A complete resection of a small, localized lymphoma may be beneficial for patients with mature B-cell NHL. However, resections at the expense of functional deficits or risks of significant surgical morbidity, including delay in initiating systemic chemotherapy, are not justified.

With the available routine diagnostic tools, a needle aspiration of a pathologically enlarged node is generally not adequate to provide sufficient material for complete pathologic examination and should be reserved for exceptions, such as when a more invasive procedure would represent an undue risk for the patient.

TABLE 53-12 St. Jude Staging System for Pediatric Non-Hodgkin Lymphoma

Stage	Definition
I	A single tumor (extranodal) or involvement of a single anatomic area (nodal), with the exclusion of the mediastinum and abdomen
II	A single tumor (extranodal) with regional node involvement Two or more nodal areas on the same side of the diaphragm Two single (extranodal) tumors, with or without regional node involvement on the same side of the diaphragm A primary gastrointestinal tract tumor (usually in the ileocecal area), with or without involvement of associated mesenteric nodes, that is completely resectable
III	Two single tumors (extranodal) on opposite sides of the diaphragm Two or more nodal areas above and below the diaphragm Any primary intrathoracic tumor (mediastinal, pleural, or thymic) Extensive primary intraabdominal disease Any paraspinal or epidural tumor, whether or not other sites are involved
IV	Any of the above findings with initial involvement of the central nervous system, bone marrow, or both

Modified from Murphy SB: Classification, staging and end results of treatment of childhood non-Hodgkin's lymphomas: dissimilarities from lymphomas in adults. Semin Oncol *7:332–339, 1980.*

The aim of staging procedures is to identify all disease sites to inform therapeutic decisions, response assessment, and follow-up monitoring. The St. Jude staging system, developed in the late 1970s, is widely accepted for the staging of childhood NHL (Table 53-12).[277] The St. Jude staging system is primarily based on the clinicopathologic features of the main NHL subtypes of childhood LL and BL. It takes into account the different patterns of disease spread of these disorders as compared with Hodgkin lymphoma, especially the more common extranodal involvement. The definition of stages is determined by the number and anatomic pattern of disease sites, their resectability, and the involvement of the bone marrow and CNS. Lymphoblastic neoplasms are considered to be acute lymphoblastic leukemia (ALL) if there are 25% or more lymphoblasts in the bone marrow. For BL, infiltration of the bone marrow with more than 25% lymphoma cells is characterized as B-cell or Burkitt-cell leukemia, also referred to as *B-ALL*. The St. Jude staging system has proven useful for the stratification of therapy intensity for the treatment of these entities. For other entities, such as ALCL, its usefulness for treatment stratification is less well defined.

Lymphoblastic Lymphoma

Neoplasms of the precursor B and T cells occur in two different clinical patterns, as ALL or as LL. Conventionally, ALL and LL are separated by the degree of bone marrow involvement. Cases with at least 25% lymphoblasts in the bone marrow with or without extramedullary disease are diagnosed as ALL, whereas those with extramedullary manifestations and less than 25% bone marrow lymphoblasts are referred to as LL. The WHO classification system categorizes the disease as T-lymphoblastic leukemia/lymphoma and B-lymphoblastic leukemia/lymphoma, with multiple subtypes based on recurrent genetic abnormalities.[25] About 80% of children with T-cell ALL and 90% of those with T-cell LL have a mediastinal tumor at presentation. In a minority of cases, T-cell ALL occurs as bone-marrow disease alone, and 10% of T-cell LL cases have no mediastinal tumor.

Pathologic Features

T-cell LL and B-cell LL are morphologically indistinguishable. The neoplastic cells are uniform in size, with scanty or indistinct cytoplasm and nuclei larger than those of small lymphocytes with finely distributed chromatin. They are historically referred to as the *L1* and *L2 types* according to the French-American-British (FAB) Classification of Acute Leukemias.[278] Nuclear membranes may possess subdivisions of varying prominence, giving rise to a distinction between convoluted and nonconvoluted variants of LL.[237] This distinction may be merely a histopathologic nuance, however,[279] and is not included in the WHO classification.

Both precursor B-cell and precursor T-cell LLs may coexpress myeloid CD13, CD33, and rarely, CD117. A useful marker to distinguish LL of precursor B and T cells from mature B-cell and T-cell neoplasms is terminal deoxyribonucleotidyl transferase (TdT). TdT adds single nucleotides to double-strand DNA breaks during the process of immunoglobulin gene and TCR gene recombination, respectively, a process essential during precursor B-cell and T-cell differentiation.[280,281] TdT is only expressed during this process and thus is a specific marker for neoplasms of precursor B and T cells but not for mature T- and B-cell neoplasms.

ALL cases can be further subdivided according to the maturational stages of the leukemic cells, defined by the sequence of expression of antigens into pro-B, common ALL, and pre-B in the precursor B-cell ALL category and into pro-T, pre-T, thymus cortex type, and thymus medullary type in the precursor T-cell category.[282] Few data exist about whether the same subdivision is possible for LL cases.

Molecular and Cellular Biology

Few data are available on genetic findings in LL, mainly because of the lack of fresh tumor tissue appropriate for cytogenetic and molecular studies. As a result, most molecular and cytogenetic data available are derived from the study of T-cell ALL cases. Globally, xome sequencing and array comparative genomic hybridization analyses of pediatric T-cell ALL shows a broad heterogeneity in the mechanisms of T-cell transformation and a low mutation load with an average of 8.2 coding mutations per sample.[283-285]

Role of T-Cell Receptor Translocations. Classic recurring chromosomal rearrangements found in T-cell ALLs and LLs involve the *TCRB* locus (7q34) or the *TCRA/D* locus (14q11) and are generated from mistakes in the recombination process that generate functional TCRs during the development of normal thymocytes.[286-288] These translocations typically induce the aberrant expression of transcription factor oncogenes in T-cell progenitors, activating an irregular transcriptional program that interferes with normal T-cell development and contributes to leukemic transformation. Transcription factor oncogenes involved in these T-cell ALL-specific translocations include members of the basic helix-loop-helix (bHLH) family (*MYC*, *TAL1*, *TAL2*, *LYL1,* and *BHLHB1*),[289-294] the LIM- domain only (LMO) protein genes (*LMO1* and *LMO2*),[295] homeodomain genes (*TLX1/HOX11*, *TLX3/HOX11L2*, and *HOXA9*),[296-299] *MYB*,[300,301] and *NOTCH1*.[302]

Importantly, a number of chromosomal rearrangements that do not involve the TCR loci are also involved in the aberrant expression of some of these oncogenes. Thus *MYB* can be activated by a t(6;7)(q23;q34) translocation[300] or alternatively by a small intrachromosomal duplication selectively affecting the *MYB* locus in the long arm of chromosome 6.[301] The TAL1d rearrangement, a small intrachromosomal deletion that places the *TAL1* gene under the control of the promoter of the nearby *SIL* gene, is found in about 25% of T-cell ALL cases.[303] Similarly, *LMO2* can be activated by small intrachromosomal deletions in the short arm of chromosome 11.[304] Both *TAL1* and *LMO2* are often expressed biallelically in T-cell ALL cases without known alterations in their respective loci, suggesting that activation of upstream regulatory mechanisms controlling the expression of these genes may also participate in the pathogenesis of T-cell ALL.[305,306]

NOTCH1 Activation. The most characteristic molecular lesion associated with the pathogenesis of T-cell lymphoblastic leukemias and lymphomas is the aberrant activation of the NOTCH1 signaling pathway. The NOTCH signaling pathway plays a critical role in the hematopoietic system by participating at multiple stages of T-cell development.

During early hematopoiesis, NOTCH signaling is required for the commitment of multipotent hematopoietic progenitors to the T-cell lineage.[307-309] Conversely, mice harboring a conditional deletion of *Notch1* in hematopoietic progenitors fail to develop T cells and show ectopic B-cell development in the thymus.[309] In some systems, this occurs between CD4 and CD8 lineages.[310-313]

Mature NOTCH receptors (NOTCH1 through 4) are transmembrane heterodimeric proteins generated from a precursor polypeptide that is postranslationally cleaved by a furin protease in the trans-Golgi network. This first cleavage generates both N-terminal and C-terminal NOTCH fragments, which in the absence of a NOTCH signaling stimulus form a heterodimeric transmembrane protein. The N-terminal fragment of the receptor contains multiple epidermal growth factor (EGF) repeats involved in ligand interaction followed by a series of Lin12-NOTCH repeats (LNRs) that in the absence of ligand, stabilize the heterodimeric association between the N-terminal and C-terminal NOTCH fragments. The latter (membrane-bound) fragment of the receptor contains a transmembrane proximal RBPJ-associated molecule (RAM) domain followed by a series of ankyrin repeats, both of which participate in the interaction with the DNA-binding factor RBPJ, and a carboxy-terminal proline, glutamic acid, serine, and threonine (PEST) sequence responsible for the proteosomal degradation of the activated receptor in the nucleus.

The NOTCH signaling pathway is normally triggered by the interaction of a NOTCH receptor in one cell with a NOTCH Jagged 1,2 and Delta-like 1,3,4 (DSL) ligand expressed in the surface of a neighboring cell. This ligand–receptor interaction induces two consecutive proteolytic cleavages at the cell surface that release the cytoplasmic intracellular domain of NOTCH (ICN1) of the receptor from the cell membrane.[314,315] The first of these ligand-induced cleavages is mediated by extracellular metalloproteases of the A disintegrin and metalloproteinase (ADAM) family. Two ADAM proteases (ADAM10 and ADAM17) have been implicated in the activation of the NOTCH signaling pathway in different organisms.[314,315] After S2 cleavage, the resultant activated membrane-bound form of NOTCH is further processed by the γ-secretase complex that catalyzes the final endomembrane cleavage step and releases the intracellular domains of NOTCH from the membrane.

After γ-secretase cleavage, the consequent activated form of NOTCH rapidly translocates to the nucleus, where it interacts with the RBPJ DNA-binding protein. In the absence of NOTCH signals, the RBPJ transcription factor binds to the DNA in NOTCH target promoters, where it recruits transcription inhibitory factors to form a multiprotein transcriptional corepressor complex.[315] Binding of ICN1 to RBPJ displaces these repressors and recruits the MAML1 coactivator to the complex, thereby switching the activity of RBPJ from repressor to activator and inducing the transcriptional activation of NOTCH-RBPJ target genes.

The human *NOTCH1* receptor gene was originally identified as part of the t(7;9)(q34;q34.3), a rare chromosomal translocation that moves the *NOTCH1* gene next to the *TCRB* locus, leading to the aberrant expression of a truncated and constitutively active form of *NOTCH1* in about 1% of human T-cell ALLs.[302] Despite evidence that NOTCH signaling plays a major role in the development of the T-cell lineage and that aberrant NOTCH1 signaling can transform T-cell progenitors, the significance of activated *NOTCH1* in human T-cell ALL seemed limited to rare human T-cell ALLs harboring the t(7;9). This perception was quickly revised after the identification of activating mutations in *NOTCH1* in 50% of human primary T-cell ALL and LL samples and more than 80% of human T-cell ALL cell lines.[316,317,318]

Activating mutations in *NOTCH1* in human T-cell ALL are concentrated in exons 26 and 27, which encode the homodimerization (HD) domain in the extracellular portion of the receptor and in exon 34, which encodes the PEST domain in the C-terminal region of the protein. In addition, *NOTCH1* juxtamembrane expansion (JME) mutations resulting from small in-frame insertions in exon 28 introduce extra amino acids in the extracellular juxtamembrane region of the receptor in about 5% of T-cell ALLs.[319] *NOTCH1* HD and JME mutations probably operate by inducing ligand-independent activation of *NOTCH1*, whereas *PEST* mutations are predicted to result in increased levels of intranuclear active *NOTCH1* by impairing its degradation by the proteasome.[320,321] Thus both types of mutations result in increased *NOTCH1* activity (five- to tenfold over baseline). Importantly, double-mutant alleles harboring both HD and *PEST* mutations are often found in T-cell ALL samples and increase the activation of *NOTCH1* tenfold more than HD or *PEST* mutations alone (50-fold over baseline).[316]

Aberrant activation of NOTCH1 signaling in hematopoietic progenitors drives commitment to the T-cell lineage and promotes malignant transformation by inducing deregulated cell growth, proliferation, and survival. Genomic studies on the identification of *NOTCH1* direct target genes and pathways in T-cell ALL have uncovered a major role for oncogenic *NOTCH1* as a critical regulator of cell growth and metabolism in T-cell lymphoblasts.[322] Thus *NOTCH1* directly binds the promoters of numerous genes involved in protein biosynthesis and anabolic pathways through RBPJ.[322] In addition, oncogenic *NOTCH1* controls the expression of *MYC*, which further increases the expression of cell-growth genes.[321-324]

The relevance of the NOTCH-MYC regulatory axis in T-cell transformation is further supported by the identification of mutations in *FBXW7* in about 15% of T-cell ALL and LL cases.[317,318,325] This -box protein mediates the proteosomal degradation of activated *NOTCH1, MYC, JUN,* and cyclin E.[326] *FBXW7* mutations found in T-cell ALL are clustered in three critical arginine residues involved in the interaction with its target proteins. Thus mutant *FBXW7* works as a dominant negative factor to promote the stability of activated *NOTCH1,* mimicking the effect of *NOTCH1-PEST* mutations.[325] In addition mutant *FBXW7* also stabilizes *MYC,* which further enhances the NOTCH-MYC axis (see earlier) and blocks the degradation of cyclin E, which may contribute to T-cell ALL transformation by promoting cell-cycle progression.[326]

The identification of activating *NOTCH1* mutations present in patients with T-cell ALL and LL has created great interest in developing anti-NOTCH therapies as treatment of this disease.[316] These include γ-secretase inhibitors (GSIs), which block the release of activated NOTCH1 (ICN1) from the membrane, and have been proposed as potential targeted therapy in T-cell ALL and T-cell LL[316,327,328]; stapled peptides targeting the NOTCH transcriptional complex[329]; and NOTCH1-specific inhibitory antibodies that have been proposed as alternative anti-NOTCH1 therapies for the treatment of T-cell ALL and LL.[330] Notably, blocking NOTCH1 signaling with γ-secretase inhibitors can reverse glucocorticoid resistance in some T-cell ALL and LL tumors, and glucocorticoid treatment abrogates the intestinal secretory-cell metaplasia and gastrointestinal toxicity associated with systemic inhibition of NOTCH signaling, supporting the use of anti-NOTCH1 therapies and glucocorticoids in combination in the clinic.[327,328]

MYC. The *c-MYC* oncogene has been implicated in the pathogenesis of T-cell ALL by the t(8;14)(q24;q11) translocation that induces aberrantly high levels of *MYC* expression in T-cell progenitors.[331,332] Furthermore the prominent role of *MYC* in T-cell transformation is reinforced by the identification of *MYC* as an important direct transcriptional target of *NOTCH1*[322-324] and by the identification of *FBXW7* mutations that contribute to increased *MYC* levels by blocking the proteosomal degradation of the MYC protein.[325,326]

***TAL1, TAL2, LYL1,* and *BHLHB1* bHLH Factors and *LMO1* and *LMO2* Transcriptional Oncoproteins.** *TAL1* is a class II bHLH factor gene aberrantly expressed in more than 60% of T-cell ALL cases.[333] *TAL1* activation can occur by means of chromosomal translocation of the *TAL1* locus in the vicinity of *TCR* genes[334] or by a small intrachromosomal deletion that places the *TAL1* gene under the control of the nearby *SIL* locus, present in 25% of T-cell ALL cases.[291] In addition, sporadic cases of T-cell ALL harbor chromosomal rearrangements that place *TAL1*-related genes such as *TAL2, LYL1*, and *BHLHB1* in the vicinity of the *TCR* loci.[292-294] Class II bHLH factors heterodimerize with the class I bHLH proteins E12, E47, HEB, and E2-2 and modulate their transactivating activities.[335] T-cell tumors expressing *TAL1* contain TAL1-E47 and TAL1-HEB heterodimers.[336] In addition, E2A-deficient mice develop T-cell lymphomas,[337,338] suggesting that TAL1 and related bHLH proteins TAL2, LYL1, and BHLHB1 may contribute to leukemia by interfering with E protein function. However, recent genome-wide mapping of TAL1 binding sites in the leukemia genome and *TAL1*-regulated genes shows a more complex scenario in which TAL1 antagonizes both activating and repressing functions of E2A in T-cell ALL.[339]

Loss of function of E2A and HEB is also believed to be the mechanism of transformation in tumors with chromosomal translocations involving the LMO protein genes, *LMO1* and *LMO2*.[304] *LMO1* or *LMO2* are frequently coexpressed with *TAL1*[333] in T-cell ALL, and TAL1-LMO2-E2A complexes are detected in human T-cell ALL cells.[340,341] Furthermore, aberrant expression of *LMO2* accelerated the leukemogenic process in transgenic mice expressing *TAL1* in the thymus.[342]

***TLX1(HOX11), TLX3(HOX11L2),* and *HOXA9* Homeobox Genes.** Homeobox (*HOX*) genes constitute an evolutionarily conserved family of transcription factors that are expressed in specific patterns during embryogenesis and are responsible for the regulation of various developmental processes in vertebrates.[343] The *TLX1 (HOX11)* family of *HOX* genes includes *TLX2 (HOX11L1)* and *TLX3 (HOX11L2)*,[344] which are characterized by the presence of a threonine in the third helix of the homeodomain; this confers specific DNA-binding properties. Both *TLX1* and *TLX3* have been linked to the pathogenesis of T-cell ALL through their identification as genes activated by chromosomal translocations. In contrast, *HOX11L1* is normally expressed in T-cell progenitors and does not seem to play a role in the transformation of normal thymocytes.[333]

TLX1 was originally isolated at the breakpoints of the recurrent t(10;14)(q24;q11) in T-cell ALL[296,297,345,346] and is aberrantly expressed in 5% of pediatric and up to 30% of adult T-cell ALL cases.[333,347-349] Like other *HOX* genes, *TLX1* plays an important role during embryonic development and acts as a master transcriptional regulator necessary for the genesis of the spleen.[350,351]

Several possible mechanisms through which aberrant *TLX1* expression might lead to malignant transformation have been proposed. In particular, the TLX1 protein is believed to function as a transcriptional regulator, a hypothesis supported by the presence of both a 61-amino acid, helix-turn-helix, DNA-binding domain (or homeodomain) and by the localization of *TLX1* in the cell nucleus.[344] In addition, *TLX1* has been shown to bind to a protein serine-threonine catalytic subunits of phosphatase 2A (PP2AC) and phosphatase 1 (PP1C). Both PP2A and PP1 are targets for oncogenic viruses and chemical tumor promoters. Thus inactivation of PP2A by *TLX1* could contribute to the transformation of T-cell progenitors.[352]

A second *HOX11* family member, *TLX3*, has been implicated in the pathogenesis of human T-cell ALL through characterization of the t(5;14)(q35;q32), a cryptic chromosomal translocation detectable only by fluorescence in situ hybridization (FISH) and chromosome-painting techniques.[298] This translocation leads to the ectopic expression of *TLX3*, possibly by bringing it under the influence of regulatory elements in the *BCL11B* gene, which is highly expressed during T-lymphoid differentiation.[298,353] In contrast to the predominance of *TLX1* expression in adult T-cell ALL cases, both t(5;14) and *TLX3* expression are present in 20% to 25% of pediatric cases but in only 5% of adult T-cell ALL cases.[347,349,354,355] As is the case for *TLX1, TLX3* plays an important role during embryonic development when it is essential for the normal development of the ventral medullary respiratory center.[356]

The TLX1 and TLX3 proteins are closely related in structure and possess a high degree of sequence identity at the amino-acid level, especially in the HOX domain, where their sequences only differ in three amino acids. The high level of structural homology in their DNA binding domains supports the hypothesis that TLX1 and TLX3 may induce T-cell ALL through the regulation of the same transcriptional targets. Gene expression profiling studies analyzing the expression signatures associated with *TLX1* and *TLX3* expressing T-cell ALLs and detailed characterization of a transgenic mouse model of T-cell ALL induced by forced expression of TLX1 in developing T cells have shown a remarkable overlap in the gene expression programs and direct transcriptional targets controlled by TLX1 and TLX3 in T-cell ALL.[357] Moreover, these studies have revealed a transcriptional repressor role for TLX1 and TLX3 in the control of gene expression and uncovered the *BCL11B* and *RUNX1* genes as prominent tumor suppressor genes downregulated by TLX1 and TLX3 in the pathogenesis of T-cell ALL.[358] Additionally, *TLX1* has been implicated in the development of aneuploidy via disruption of mitotic checkpoint mechanisms[357] and in blocking T-cell development via inhibition of *TCRA* recombination.[359]

MYB. The translocation t(6;7)(q23;q34) is a rare recurrent rearrangement that juxtaposes the *TCRB* and *MYB* loci in very young pediatric T-cell ALL cases (median age, 2.2 years).[300] The pathogenic role of *MYB* in T-cell ALL is further supported by the identification by molecular cytogenetic techniques of a short somatic duplication, which includes the *MYB* locus in 15% of T-cell ALL cases.[300,301] These abnormalities induce increased *MYB* expression, particularly in the case of the *TCRB-MYB*–rearranged leukemias. The MYB transcription factor is essential for primitive and adult hematopoiesis, including the T-cell lineage, and the *MYB* locus is a common site of retroviral insertional mutagenesis-induced leukemias; however, the specific mechanisms that mediate *MYB*-induced transformation in T-cell ALL remain to be elucidated. Notably, *MYB* is upregulated downstream of *HOXA9* and *MLL-ENL* T-cell oncogenes and is required for *HOXA9*- and *MLL-ENL*-induced leukemic transformation.[360]

***CALM*-AF10.** The t(10;11)(p13;q14-21) is a recurrent chromosomal translocation found in patients with AML and T-cell ALL. The product of this translocation is a chimeric oncogene resulting from the fusion of clathrin assembly lymphoid myeloid leukemia gene (*CALM*) and AF10.[361,362]

CALM is a ubiquitously expressed protein containing an epsin N-terminal homologous domain involved in the interaction with clathrin during endocytosis.[363] AF10 is a ubiquitously expressed transcription factor originally identified as a partner of *MLL* in AML.[364,365] *CALM*-AF10 rearrangements are present in 5% to 10% of T-cell ALL cases and seem to be particularly common in tumors with a very early block in T-cell development or those expressing TCRad.[366,367] Gene-expression profiling studies have demonstrated that *CALM*-AF10 expression is associated with high levels of *HOXA* genes, including *HOXA9*.[299,368]

MLL-ENL. Rearrangements of *MLL*, located on human chromosome 11q23, are common in infant and therapy-related leukemias and can occur in AML and ALL. These rearrangements typically generate a fusion oncogene containing the N-terminus part of *MLL* and various protein domains from more than 50 different fusion partners. The *MLL-ENL* fusion oncogene is found in rare cases of T-cell ALL and, in contrast with *MLL* rearrangements in other hematologic tumors, is associated with a favorable prognosis.[333] *MLL* is normally responsible for the maintenance of gene expression at the *HOX* paralog groups. *MLL*-fusion oncogene products disrupt the normal function of MLL and result in aberrant expression of *HOX* genes.[369,370] *MLL*-rearranged T-cell ALL cases have high levels of expression of *HOX* genes, including *HOXA9* and *HOXA10*.[333,370]

Transcription Factor Tumor Suppressors. *BCL11B* encodes for a transcription factor critically required for normal T-cell development.[371] Loss-of-function mutations and heterozygous deletions of the *BCL11B* are recurrently found in T-cell ALL, suggesting that *BCL11B* haploinsufficiency is an important pathogenetic event in T-cell leukemogenesis.[357,372] In addition, the Wilms tumor suppressor gene 1 (*WT1*) is deleted and mutated in about 10% of T-cell ALLs.[373,374] Similarly, monoallelic or biallelic deletions involving the *LEF1* locus and mutations in the *LEF1* gene are recurrently present in T-cell ALL cases.[375] Finally, *ETV6*, *RUNX1*, and *GATA3* loss-of-function mutations are characteristically present in a fraction of early-immature T-cell ALLs, a leukemia group characterized by a very early arrest in T-cell development and poor prognosis.[358,376-378]

Cell Cycle Regulators. Deletions of chromosome bands 9p21-229 involving the $p16^{INK4A}$, $p14^{\mathrm{ARF}}$, and $p15^{\mathrm{INK4B}}$ tumor suppressor genes are the most common abnormality found in T-cell lymphoblastic tumors.[379,380] p15 and p16 are involved in cell-cycle regulation by inhibiting cyclin-CDK complexes, whereas $p14^{ARF}$ is a negative regulator of TP53. Thus loss of these tumor suppressors affects both the control of cell proliferation and cell survival.

Chromosomal translocations targeting the cyclin D2 (*CCND2*) locus at chromosome band 12p13 and the *TCRB* or *TCRAD* loci result in high levels of *CCND2* overexpression. *CCND2* expression is normally confined to early (double-negative) stages of thymocyte differentiation and is replaced by *CCND3* in more mature (double-positive) cells, suggesting that sustained expression of CCND2 in *CCND2*-rearranged T-cell ALL cases is oncogenic.[300]

Chromatin Remodeling Tumor Suppressor Genes. The polycomb repressive complex 2 (PRC2) is the “writer” of lysine 27 trimethylation on Histone 3 (H3K27me3), a major chromatin mark associated with transcriptional silencing. Loss-of-function mutations and deletions of *EZH2* and *SUZ12* genes encoding two critical components of the PRC2 complex are found in about 25% of T-ALLs.[377,381] In addition, *PHF6*, a plant homeodomain (PHD)–containing factor involved in epigenetic regulation of gene expression is mutated and deleted about 16% of pediatric T-cell ALL cases.[382]

Genetic Alterations Driving Activation of Oncogenic Signaling Pathways. The *PTEN* tumor suppressor gene, which encodes a central negative regulator of the PI3K–AKT pathway, is mutated and deleted in 5% to 10% of T-cell ALL cases,[383] and prototypical activating mutations in *NRAS*-activating mutations are common in early immature T-cell ALLs.[376,377,384] In addition, deletions and mutations in the neurofibromatosis type 1 (*NF1*) gene, which encodes a negative regulator of Ras signaling, are found in 3% of T-cell ALLs.[385] Aberrant JAK signaling drives T-cell transformation in T-cell ALLs harboring the t(9;12)(p24;p13) translocation, a rare rearrangement encoding a constitutively active *ETV6-JAK2* oncoprotein.[386] Moreover, activating mutations in *JAK1* and *JAK3* and the *IL7R* gene resulting in constitutive activation of the JAK-STAT signaling are present in approximately 15% of T-cell ALLs.[377,387-390]

Other Genetic Alterations. Numerous additional genes and pathways whose mechanism of action remains to be fully clarified are altered in T-cell ALL. Among these, recently identified genetic-lesion mutations affecting the ribosomal proteins RPL5, RPL11, and RPL10 including recurrent alterations of Arg98 in RPL10 are particularly intriguing and suggest a role for disruption of ribosomal function in T-cell transformation.[283]

Clinical Characteristics

Children and adolescents with LL most commonly show signs and symptoms of mediastinal disease such as cough, shortness of breath, or orthopnea. Patients may have severe distress that is sometimes made worse by the effects of pleural or pericardial effusions. Patients may also have painless adenopathy, most often cervical or supraclavicular, although the disease can be widely disseminated and involve the liver and spleen. Those with B-cell LL more often show limited-stage disease of skin, isolated node, or bone. Disease limited to the skin most commonly involves the scalp.[391] Patients may have symptoms related to CNS disease, including signs associated with increased intracranial pressure such as headache, nausea and vomiting, and visual changes or with cranial nerve palsies.[267] Many who are subsequently found to have CNS will not have had preceding symptoms. By definition, patients with LL have less than 25% bone marrow involvement. Most patients therefore do not exhibit signs or symptoms associated with severe pancytopenia, and most commonly the complete blood count (CBC) is normal or near normal.[392] Involvement of the testes for patients with LL is relatively rare. Table 53-13 describes the clinical features at the time of diagnosis in patients with LL in selected cooperative group studies.

Treatment and Outcomes

The treatment of children and adolescents with LL is largely based on the strategies and protocols developed for the treatment of ALL. Outcomes for selected

TABLE 53-13 Presenting Features in Children and Adolescents with T-Cell Lymphoblastic Lymphoma

	% Male	% with Mediastinal Mass	% with CNS Disease	% with Bone Marrow Disease

cooperative groups trials are presented in Table 53-14. Considerations for therapy include immunophenotype, stage including CNS involvement, and more recently, the impact of the presence of minimal disease involvement of the bone marrow at the time of diagnosis.[393] Other clinical factors such as age, gender, and LDH as well as tumor response were not found to be prognostic in the Berlin-Frankfurt-Munster (BFM) studies. Patients with low-stage disease have survival rates that exceed 90%, whereas the rate for those with stage 3 or 4 disease approaches 80%.[394,395]

Patients with stage 1 and 2 disease account for a minority of patients with LL. Approximately 75% of the low-stage group has B-lineage disease.[395] Early studies of localized NHL evaluating 9 weeks versus 8 months of therapy showed that those with LL had a significantly worse outcome than other NHL phenotypes, with evidence of some benefit for longer therapy in this subgroup.[396] Studies that have included patients with all stages of LL have consistently reported favorable outcomes for those with limited disease with EFS rates of 73% to 100%.[397] The largest series of patients with stage 1 and 2 LL disease treated in a uniform manner comes from the COG study A5971. Patients were assigned to a CCG-BFM–like ALL regimen that included 24 months of therapy, intensive intrathecal therapy, and no radiation.[395,398] Seventy five percent of the patients had pre-B immunophenotype, and the majority had disease in their head and neck region, involving skin and nodal tissue with a minority who had isolated bone disease. The 5-year EFS and OS rates were 90% and 95%, respectively.

The majority of patients with LL have advanced-stage disease at diagnosis and have the T-cell phenotype. The most effective regimens for this group of patients are based on regimens adopted from the treatment of children with ALL. Most treatment protocols include corticosteroids, vincristine, anthracyclines, L-asparaginase, and cyclophosphamide; and methotrexate, cytarabine, 6-mercaptopurine, and 6-thioguanine; and some include epipodophyllotoxins. Most involve induction, consolidation, and maintenance phases of chemotherapy and prolonged treatment lasting approximately 2 to 3 years. Radiotherapy to sites of disease outside the CNS is not generally used in contemporary treatment protocols.

In the context of multidrug therapy, isolating the importance of specific agents is challenging. There is mixed evidence that the use of high-dose methotrexate is important in the treatment of children with advanced-stage disease. The BFM90 trial, which included 4 courses of 5 gm/m^2 of methotrexate in consolidation, had excellent outcomes with a 5-year EFS rate of 90% to 95%.[394] The POG9404 study evaluated the addition of high-dose methotrexate to an intensive ALL backbone for patients with T-cell ALL and T-cell LL. The 5-year EFS rate was better for those who received high-dose methotrexate in patients with T-cell ALL but there was no measurable difference for those with T-cell LL.[399] A recent COG study evaluating the impact of induction intensification and the use of high-dose methotrexate in consolidation found no benefit to either intervention.[400] Evidence for the efficacy of L-asparaginase in patients with T-cell LL can be derived from a randomized study conducted by the former POG.[401] Patients with T-cell LL receiving weekly L-asparaginase after induction had a higher EFS rate than controls. Dexamethasone instead of prednisone in induction resulted in improved outcome of children suffering from ALL at the expense of higher toxicity.[402] Randomized BFM-based trials as to whether dexamethasone in induction can also further improve the EFS rate of patients with T-cell LL are ongoing.

Oral 6-mercaptopurine and methotrexate are basic elements of maintenance therapy during remission; they are administered for a treatment duration of 18 to 24 months from the start of chemotherapy. With the exception of the BFM strategy, additional agents (vincristine and steroids) and multiple intensification pulses of different composition are used in many study protocols. When comparing overall results of studies, there is little evidence for a beneficial effect of intensification of maintenance.

CNS-directed chemotherapy including high-dose methotrexate and intrathecal therapy without prophylactic cranial irradiation is sufficient for prevention of CNS relapse in patients with advanced-stage LL without overt CNS disease.[399,403,404,405] In the NHL BFM 95 study, including high-dose methotrexate (5 g/m^2 IV, four times daily) and 11 doses of intrathecal methotrexate but no cranial radiotherapy (CRT), both disease-free and CNS relapse–free survival rates of patients were not significantly inferior to the historic control group of the preceding NHL BFM86 and BFM90 trials, in which patients received prophylactic CRT.[403] High-dose methotrexate therapy also appears efficacious to prevent relapse in the testes.[394]

For patients with overt CNS disease, 18 to 24 Gy CRT, in addition to aggressive systemic chemotherapy, is highly effective in preventing CNS recurrences.[265,394,397] In the BFM studies, patients with CNS-positive LL had EFS rates comparable to patients who were CNS-negative when receiving high-dose methotrexate (5 g/m^2 IV infusion) over 24 hours and intrathecal therapy followed by CRT with 18 Gy.[265]

Therapy for Patients with Relapsed Disease

The outcome for patients with relapsed LL is poor.[406] The general strategy for these patients includes intensive reinduction therapy, and for those patients with responsive disease, ideally a second CR to proceed to SCT. One of the main reasons for poor outcomes is the failure of disease, once it has relapsed, to respond to further therapy. There is no standard reinduction regimen. Various combinations have been described including ifosfamide, carboplatin, and etoposide (ICE)[407] and dexamethasone, etoposide, cisplatin, cytarabine, and L-asparaginase (DECAL).[408]

Nelarabine, a nucleoside analogue, has been shown to have activity as a single agent in children with relapsed and refractory T-cell malignancies.[409] Nelarabine in combination with etoposide and cyclophosphamide has been described in a small case series as being safe and effective. In this series seven of the seven patients had some evidence of disease response and five of seven obtained CR.[410] Nelarabine, in addition to T-cell ALL backbone therapy, is being tested for safety and efficacy in the current phase III randomized trial for children with newly diagnosed high-risk T-cell ALL and T-cell LL within the COG.

The data for SCT in patients with relapsed LL are limited. Unlike for other types of NHL, there is no clear role for autologous SCT in patients with relapsed LL.[411] In a report from the BFM, no patient with relapsed LL who did not proceed to allogeneic SCT was a long-term survivor. The majority of patients did not undergo SCT because of nonresponsive disease. Of the nine patients who were able to undergo allogeneic SCT, four remain in second CR.[406]

Mature B-Cell Neoplasms

Of the numerous subtypes of neoplasms of mature B cells, only two commonly occur during childhood and adolescence, BL and DLBCL. All others are rare in children. Combined, these two entities account for approximately 60% percent of NHL in children and adolescents.

Pathologic Features: Burkitt Lymphoma

Classic BL is composed of monomorphic medium-sized cells with deep basophilic cytoplasm and round to ovoid nuclei, with granular dispersed chromatin and multiple nucleoli corresponding to L3 morphology according to the FAB classification.[278] Lipid vacuoles are commonly present in the cytoplasm and the nuclei but are not mandatory. Numerous mitotic and apoptotic cells are usually seen. On histomorphology, a “starry sky” pattern is usually present, created by the intercalation of numerous macrophages that have ingested apoptotic cells. Using proliferation-associated markers such as Ki67, the growth fraction is high and can be up to 100%.[39]

BL cells invariably express the B-lineage antigens CD19, CD20, CD22, and CD79a and surface immunoglobulin and are negative for CD5, CD23, and TdT.[26] The expression of the germinal center markers BCL6 and CD10 points to a germinal center origin of BL cells.[412]

The 2008 WHO classification eliminated the category of Burkitt-like lymphoma.[238] Two provisional diagnostic groups were added: B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and BL and B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and CHL[39] that account for disease whose morphologic, immunologic and molecular phenotype lies between classic disease groups.

Molecular and Cellular Biology. BL is universally characterized by a characteristic gene expression signature that includes the aberrant expression of *MYC*.[413] This cellular oncogene encodes a helix-loop-helix transcription factor involved in the control of multiple cellular processes that contribute to cellular transformation, including cell growth, division, death, metabolism, adhesion, and motility. Chromosomal translocations characteristic of BL juxtapose the *c-MYC* locus in chromosome band 8q24 with strong enhancers from the immunoglobulin genes and drive high levels of *MYC* expression.[414,415] In 80% of BL cases, the t(8:14)(q24;q32) translocation places *MYC* in the vicinity of the *IGH* locus.[416] In 15% of cases, the translocation partner is the *IGK* locus at chromosome 2p11, whereas the remaining 5% of cases involve the *IGL* locus at chromosome 22q11. BL exhibits a distinct gene-expression profile characterized by the high-level expression of *MYC* target genes, which allows accurate differentiation of BL from other NHL subtypes such as DLBCLs.[413,417]

Tumors with the t(8;14) show differences in the location of the breakpoints relative to the *MYC* gene and the *IGH* genes, which are strongly associated with the geographic origin of the patient.[418-422] In endemic BL, the chromosome 8 breakpoints are found up to 100 kb 5′ from the *MYC* exon 1, whereas the chromosome 14 breakpoints occur most often in the *IGH* joining regions (J_Hs). In contrast, in sporadic and AIDS-associated BL, the chromosome 8 breakpoints are most often located between *MYC* exons 1 and 2, and those in chromosome 14 are found in the *IGH S*μ switch region. In cases with *MYC* rearrangements involving the light-chain immunoglobulin genes, the breakpoints on chromosome 8 are located at variable distances from the 3′ of the *MYC* locus,[423,424] and the breakpoints on chromosomes 2 and 22 are located 5′ from the constant region of the *IGK* and *IGL* genes. These findings suggest that in sporadic and AIDS-associated BLs with the t(8;14), the chromosome 14 breakpoints are generated during immunoglobulin-class switch recombination. This supports a germinal center B-cell origin for these tumors. In contrast, in endemic BL, the breakpoints on chromosome 14 originate during RAG-mediated variable-diversity-joining (V[D]J) recombination, suggesting that these tumors most probably derive from pre-B cells, which normally express *RAG* genes, or from germinal center B cells undergoing *RAG* gene reexpression.[425] In addition, the breakpoints of the translocation t(8;14) also differ between EBV-positive and EBV-negative cases, with breakpoints outside the *MYC* locus on chromosome 8 associated with EBV positivity and breakpoints within the *MYC* locus being identified in EBV-negative cases.[419] Notably, immunoglobulin gene analysis has revealed two distinct cells of origin for EBV-positive and EBV-negative cases, irrespective of the subtype (endemic, sporadic, or immunodeficiency-associated BL), suggesting that EBV status rather than the geographic distribution determines the biology of the disease.[426]

The first exon and first intron of *c-MYC* contain negative transcription regulatory sequences.[427,428] These negative regulators of *MYC* expression are removed in sporadic BL, with t(8;14) breakpoints located in *MYC* intron 1. In contrast, in endemic BL and sporadic BL with light-chain gene translocations, the chromosomal breakpoints are located 5′ or 3′ to the *MYC* locus, respectively. However, in these tumors, the *MYC* exon 1 and intron 1 are often mutated and show loss of the negative transcriptional regulatory elements located in these regions.[429,430] Thus even though the immunoglobulin enhancers drive high levels of *MYC* ribonucleic acid (RNA) expression, *MYC* levels are further increased in BL by the deletion and/or mutation of negative regulatory sequences within the *MYC* locus.

Additionally, BL tumors often show mutations of *MYC* at codon 58. These mutations stabilize the MYC protein by disrupting a critical threonine phosphorylation site involved in the proteosomal degradation of this transcription factor.[431-434]

Other Recurrent Genetic Abnormalities. Recent genomic studies have uncovered novel, highly prevalent, genetic alterations involved in the pathogenesis of BLs.[54,435-437] Most prominently, 70% of sporadic and immunodeficiency-associated BLs and 40% of endemic tumors show somatic mutations that activate the transcription factor TCF3 or disrupt the activity of its negative regulator ID3, highlighting a major role for *TCF3* activation in B-cell transformation. *ID3* mutations (38% to 68%) are more common than *TCF3* mutations (11%). Mechanistically, *TCF3* modulates essential genes for germinal center function and can activate the prosurvival PI3K pathway by intensifying B-cell receptor signaling. In addition, about 40% of sporadic BLs and a minority of endemic tumors show mutations in the *CCND3* cell-cycle regulator, resulting in highly stable CCND3 isoforms that drive cell-cycle progression. These studies also confirmed the presence of mutations in the *TP53* tumor-suppressor gene in about 30% of BLs.[438,439] Notably, *MYC* overexpression can induce apoptosis by TP53-dependent and TP53-independent mechanisms.[440-442] Thus the loss of *TP53,* which has prominent roles in the control of programmed cell death, may enhance the transforming effects of *MYC*. Additional highly prevalent mutant genes in BL include those encoding the DDX3X RNA helicase, the SMARCA4 SWI/SNF chromatin regulator, the NCOR2 transcriptional corepressor, the PDCD11 ribosomal RNA maturation factor and the GNA13 G protein signaling factor.

Role of Epstein-Barr Virus. EBV infection is present in 90% of endemic BL cases, 20% of sporadic BL cases, and about 40% of HIV-associated BL cases.[423] Although molecular data have indicated that EBV infection precedes or occurs concomitantly with B-cell transformation,[443] the specific mechanisms whereby EBV infection contributes to the pathogenesis of BL have not been fully elucidated. However, the virally encoded *EBNA-1* gene may play an important role, because it can induce B-cell lymphomas in transgenic mice[444] and has been shown to be essential for EBV-induced B-cell transformation in vitro.[445,446]

Pathologic Features: Diffuse Large B-Cell Lymphomas

DLBCLs are composed of large, transformed lymphoid cells derived from germinal-center and postgerminal-center B cells.[39] DLBCL cells consistently express pax5, CD79a, and CD20, whereas expression of all other B-lineage markers varies. Morphologically, DLBCLs are diverse and can be subdivided into three distinct variants. The centroblastic variant is composed of medium-sized to large cells with basophilic cytoplasm, oval to round nuclei, and two to four membrane-bound nucleoli. The immunoblastic variant has a preponderance of immunoblasts with centrally located nucleoli and basophilic cytoplasm. The anaplastic variant has very large, round, oval, or polygonal cells with bizarre pleomorphic nuclei, which may resemble Reed-Sternberg cells and commonly express CD30. However, this variant is biologically unrelated to ALCL. The centroblastic variant is the most common histiologic type of DLBCL in children.

Other subtypes of DLCBL have been described, including T-cell and histiocyte-rich large B-cell lymphoma. Most cells of this type are nonneoplastic T cells, with or without histiocytes; fewer than 10% of the infiltrate are neoplastic B cells, which resemble immunoblasts, centroblasts, Hodgkin cells, or L&H cells of NLPHL. Because of the predominance of reactive cells, this variant may be misdiagnosed as representing a reactive lymph node. Also, the distinction from NLPHL may be difficult, and an overlap between both cannot be completely excluded.[39]

Complex cytogenetic abnormalities are observed in DLBCL. So far, no entity-specific, nonrandom chromosomal translocations have been described for this subgroup, which may reflect its heterogeneity. In many cases, translocations, including the *c-MYC* locus 8q24, are observed, as well as abnormalities in 3q27, where the protooncogene *BCL6* is located.[447] Based on gene expression profiling, two main subtypes of DLBCL can be distinguished: germinal center B-cell–like (GCB) DLBCL and activated B-cell–like (ABC) DLBCL.[448] The subdivision of DLBCL cases into GCB and ABC subtypes by gene expression analysis could be reproduced by means of immunohistochemistry, applying the germinal-center cell markers CD10 and BCL6, and the postgerminal center marker MUM1.[449] CD10 expression assigned cases to the GCB type independently of *MUM1* expression, but in CD10-negative cases, *BCL6* positivity and negativity for *MUM1* were associated with GCB type. Although indistinguishable from adult DLBCL cases in terms of morphology, DLBCLs in children appear to comprise a biologically distinct subgroup of germinal center B-cell lymphomas.[450] In contrast to adult DLBCL, pediatric DLBCL is predominantly of germinal center origin (6 : 1) but differs from adult DLBCL of the GCB type in that it invariably lacks t(14;18).[451] Chromosomal abnormalities in 8q24 including *MYC* rearrangements and gain or amplification of *MYC* are present in 31% and in 50% of pediatric DLBCL cases.[451,452] Additional common chromosomal alterations include losses at 3q and 6q and gains at 1q and 12q.[451,452] In addition, although array-based comparative genomic hybridization (aCGH) analysis has identified genetic lesions shared between adult and pediatric DLBCL (+12q15, +19q13, and −6q), these studies have also highlighted abnormalities unique to the pediatric cases (−4p14, −19q13.32, and +16p11.2).[451]

Clinical Characteristics

In 1958 Denis Burkitt described a “sarcoma involving the jaw in African children,” which a short time later was shown by O’Connor to be a lymphoma. Burkitt recognized the endemic nature of the disease.[251] In 1964 viral particles subsequently known as *EBV* were identified in the tumor.[252] Most NHL cases in children in North America and Europe were morphologically indistinguishable from BL. Because there was no geographic limitation and most cases were not associated with EBV infection, they were referred to as *sporadic BLs*, in contrast to the endemic BL of central Africa. According to the WHO classification, three clinical subtypes are recognized. These are morphologically indistinguishable but differ in clinical presentation and biology and include endemic BL, sporadic BL, and immunodeficiency-associated BL.[39] Endemic BL occurs in equatorial Africa, Papua New Guinea, and equatorial regions of South America. In up to 95% of endemic BL cases, the tumor cells carry the EBV genome.[453] Sporadic BL occurs throughout the world in much lower incidence rates as compared with endemic BL. Nevertheless in industrialized countries, BL lymphoma is the most common subtype of NHL in childhood and adolescence and the most common of the mature B-cell neoplasms. In contrast to areas with endemic BL in central Europe, only 10% to 15% of patients with pediatric BL carry the EBV genome.[253,254] Immunodeficiency-associated BL occurs most often in patients with HIV infection but also in patients after solid organ transplantation. The incidence of EBV infection in immunodeficiency-associated BL in North American patients is less than 40%. The incidence of immunodeficiency-associated BL has fallen somewhat with the use of antiretroviral therapy.[416]

The pattern of disease at presentation varies between sporadic and endemic BL and DLBCL. The most common site of disease at presentation for patients with sporadic BL is the abdomen.[454] Common presenting symptoms include abdominal distension, nausea and vomiting, gastrointestinal bleeding, and abdominal pain. A classic although relatively rare presentation of patients with BL is intussusception, where ultrasound imaging reveals evidence of a tumor as a “lead point mass” in the small bowel.[455] Other common sites include the head and neck including cervical nodes, tonsils, and sinuses.

Patients with Burkitt leukemia most often present as a leukemic disease in combination with large tumors.[456] However, in some cases the disease can be confined to the bone marrow without any extramedullary involvement.

In children with Burkitt leukemia, the peripheral blood may show prominent vacuolate lymphoblasts. However, in contrast to pediatric early B-cell ALL, the blast count in the peripheral blood rarely exceeds 30,000/L. In general the degree of anemia and thrombocytopenia is less severe compared with other types of pediatric leukemia, reflecting a lesser degree of bone-marrow invasion.

Patients with endemic BL have classically presenting symptoms of jaw disease, most commonly found in younger children. In addition periorbital findings and abdominal involvement are common. The incidence of symptomatic CNS disease, particularly paraplegia, is much higher than that in the developed world.[265] In low-income countries the majority of patients present with advanced disease, and many are malnourished at the time of diagnosis.[457] By contrast, patients with DLBCL most often have symptoms of nodal disease including involvement of peripheral nodes as well as those in the abdomen and mediastinum. The majority have advanced stage disease, although CNS and bone marrow involvement is rare.

Treatment and Outcome of Mature B-Cell Neoplasms

In adult patients therapy for those with DLBCL and those with BL differs. In children the chemotherapy regimens developed and utilized for patients with BL, who make up of the majority of patients, have proven to be equally effective for those with DLBCL. Hence in the majority of contemporary pediatric protocols the two diseases are treated identically.

Chemotherapy for BL was pioneered in Africa, where Denis Burkitt achieved remission in children with BL with single or few doses of cyclophosphamide, low-dose methotrexate, or vincristine.[458] He recognized that children with a small tumors were more likely to achieve CR than those with large tumors, which suggests a relationship between tumor mass and response.[459] The next important step was the introduction of the combination chemotherapy of cyclophosphamide, vincristine, methotrexate, and cytarabine, which proved not only efficacious for African children with endemic BL but also for American patients with sporadic BL.[460,461] The high incidence of CNS relapses and the failure of cranial irradiation to prevent them was described by this group, leading to the introduction of combined intrathecal chemotherapy.[460,462,463] Based on the African experience, Ziegler and colleagues first explored the principle of dose intensity and achieved CRs with high-dose chemotherapy in American patients with BL that was unresponsive to lower dose therapy.[464]

In the 1980s, treatment strategies were further improved by the emerging information about the peculiar biologic features of BL. A most important characteristic regarding therapeutic strategy is its high proliferation activity. BL cells cycle extremely rapidly, with an estimated generation time of only 25 hours.[465] It can be estimated that within 48 to 72 hours, every Burkitt cell is likely to traverse the cell cycle, thereby encompassing a period of greatest sensitivity to cytotoxic treatment.[466-468] Based on this knowledge, combination chemotherapy courses were designed based on the principle of maintaining—by means of fractionated administration or continuous infusion—cytotoxically active drug concentrations for the length of time needed to affect as many lymphoma cells as possible during the vulnerable active cell cycle.[469-472] Therapeutic regimens that adhere to the principle of rapidly repeated cycles of dose-intensive combination chemotherapy have resulted in a dramatic increase in the cure rate over the last several decades from less than 40% to greater than 85%.[473]

Although there are few randomized trials testing the impact of individual drugs there is considerable evidence that cyclophosphamide and methotrexate may be key agents. Monotherapy with methotrexate or with cyclophosphamide, with or without low-dose methotrexate and vincristine can induce durable remissions in BL.[458,461,474] The important role of methotrexate can be extrapolated from the effect of different dosages. In patients with stage III disease and high tumor mass (LDH >500 U/L, approximately twice or more the upper limit of normal for age), and in patients with Burkitt leukemia, a 10-fold increase of the dose of methotrexate from 0.5 to 5 g/m^2 resulted in significantly improved outcome.[456,475] Similarly, the elevation of the dose of methotrexate from 3 to 8 g/m^2 in the Societe Francaise d'Oncologie Pediatrque-Lymphoma Maligancy B (SFOP-LMB) protocols resulted in an excellent outcome of patients with advanced-stage BL, including those with CNS involvement.[266,476,477] Comparatively little evidence exists as to the role of corticosteroids and anthracyclines. In a CCG study of the 1980s, addition of daunomycin to the combination of cyclophosphamide, vincristine, methotrexate, and prednisone (COMP) did not improve the outcome of patients with advanced-stage non-LL as compared with COMP alone.[478]

The therapeutic strategies used for children with mature B-cell lymphomas are associated with significant short-term toxicity including severe mucositis and risks of infections. The mucosal toxicity is caused primarily, but not solely, by high-dose methotrexate. In patients with significant mucositis together with the severe neutropenia, risks of bacteremia (often from intestinal flora) are high. Patients with advanced disease stages are at the greatest risk. For these patients, the rate of toxicity-induced death is up to 5%, even in the most recent treatment studies.[266,475] Postchemotherapeutic application of granulocyte colony-stimulating factor (G-CSF) had no effect on treatment-related toxicity, as demonstrated in a randomized trial.[479] Toxicity and the risk of toxic death is greatest during and after the first treatment course.

Risk stratification for patients with BL and DLBCL is of critical importance, allowing for allocation to the most appropriate treatment regimen. Treatment regimens vary in intensity based on the number of drugs used, their dosage, and the number of treatment courses that have obvious implications for both short- and long-term toxicities. Criteria used to stratify patients include stage, LDH level, and CNS involvement but have differed somewhat between cooperative groups (Table 53-15). Other prognostic factors include poor response to "reduction therapy" with cyclophosphamide, prednisone, and vincristine; poor-risk cytogenetics; and mediastinal disease.[473,480] The genetic changes detectable by karyotype associated

TABLE 53-15 Treatment Stratification and Results in Two Large Multicenter Trials of Pediatric Mature B-Cell Neoplasms

Group	Definition	Patients, N (% of all patients)	EFS (%)	Chemotherapy Courses (Randomized Study Questions)	Outcome
FAB-LMB96 Trial[269,483,606]					
A	Stage I, resected; stage II, abdominal, resected	132 (12%)	98 (4 year)	COPAD-COPAD	2 courses of therapy and no intrathecal treatment is curative in patients with resected localized disease.
B	Stage I + II not resected; Stage III Stage IV with bone-marrow blasts <25%	657 (67%)	90 (4 year)	COP-COPADM1-COPADM2-CYM-CYM-M1 (randomization for complete responders after COPADM1 to therapy reduction verus standard)	Therapy reductions of 50% dose reduction of cyclophosphamide and omission of M1 was equally as efficacious as the standard regimen.
C	>25% bone-marrow blasts and/or CNS+ nonresponder to COP of group B	235 (21%)	79 (4 year)	COP-COPADM1-COPADM2-CYVE1-CYVE2-M1-M2-M3-M4 (randomization for complete responders after COPADM1 + M2)	Therapy reductions of reduced intensity “mini-CYVE” and omission of M2, M3, and M4 resulted in inferior outcome.
NHL-BFM95484					
R1	Stages I + II, resected	48 (10%)	94	A-B (randomization: methotrexate IV over 24 hr vs. 4 hr)	Methotrexate over 4 hr less toxic, equally efficacious
R2	Stages I + II, not resected; stage III, LDH <500/U/L	233 (46%)	94	p-A-B A-B (randomization: methotrexate IV over 24 hr vs. 4 hr)	Methotrexate over 4 hr less toxic, equally efficacious
R3	Stage III, LDH 500-999 U/L Stage IV and LDH <1000U/L and CNS–	82 (16%)	85	p-AA-BB-CC-AA-BB (randomization: methotrexate in AA, BB IV over 24 hr vs. 4 hr)	Methotrexate over 4 hr less toxic but in this group less effective
R4	Stage III + IV and LDH ≥1000 U/L and/or CNS+	142 (28%)	81	p-AA-BB-CC-AA-BB-CC (randomization: methotrexate in AA, BB IV over 24 hr vs. 4 hr)	Methotrexate over 4 hr less toxic but in this group less effective

with an inferior outcome are +7q and deletion (13)q.[452] The presence of minimal disseminated disease in the bone marrow at diagnosis has also been found to be associated with a worse prognosis.[481] The use of bone marrow monitoring for assessment of responses to therapy and persistence of minimal residual disease may be of importance in the future.[482] Within pediatric protocols neither age (older or younger than 15 years) or histology (BL versus DLBCL) is prognostic.

Patients with localized disease have excellent outcomes with an EFS rate approaching 100%. The international study FAB-LMB96 enrolled patients of all disease stages. One hundred and thirty two patients with resected stage I or completely resected abdominal stage II disease were treated with two courses of cyclophosphamide, vincristine, prednisolone, and doxorubicin (COPAD) without intrathecal therapy. The 4-year EFS and OS rates were 98.3% and 99.2%, respectively.[483] In the NHL BFM95 study, 48 patients with completely resected stage I or II disease were treated with two courses of therapy which include dexamethasone, vincristine, ifosfamide, cytarabine, etoposide, cyclophosphamide, doxorubicin, and methotrexate in addition to intrathecal triple therapy and had a 3-year EFS rate of 94%.[484]

Patients defined as having intermediate-risk disease according to the FAB-LMB protocols, the “group B” patients (see Table 53-15) compromise the largest group. These are individuals with unresected stage I or II disease, those with stage III or IV disease without CNS involvement, or those with bone marrow disease meeting criteria for Burkitt leukemia. This patient group also has an excellent outcome with modern intensive therapy. Patients in the FAB-LMB96 study were randomized in a 2-×-2 factorial design to evaluate two-dose reduction questions, reduction of cyclophosphamide dose, and removal of a maintenance cycle of therapy. Six hundred and fifty seven patients with intermediate-risk disease were randomized. The 4-year EFS and OS rates were 90.9% and 93.4%, respectively, with no significant difference across study arms. Patients in the NHL-BFM95 study with stage I or

II unresected disease or those with stage III disease with a low LDH who received four courses of chemotherapy also had a similarly favorable outcome with 3-year EFS rate of 94%.[484]

The use of LDH for stratification of treatment intensity is a major difference between the FAB-LMB and the NHL-BFM studies (see Table 53-15). The serum concentration of LDH, considered a proxy for tumor mass, may vary largely in patients at the same stage, especially for those with stage-III BL. Although not used prospectively for risk assignment on the FAB-LMB study, analysis of patients enrolled showed that LDH greater than two times the institutional upper limit of normal was a significant risk factor for an inferior outcome.[480] The current international study of childhood B-cell lymphoma, InterB-NHL 2010 Ritux defines a group of patients with high-risk disease in part based on LDH.

Patients with high-risk disease in the LMB studies have been defined as those with CNS disease (parenchymal brain involvement, cranial nerve palsies, or CSF disease) or those with Burkitt leukemia (bone marrow with >25% blasts). BL accounts for 70% to 80% of the patients in this group. The EFS and OS rates of this patient group approaches 80%. Reduction of therapy in patients with high-risk disease has not been successful, as it has been for the low- and intermediate-risk groups. In the FAB-LMB96 study the 4-year EFS rate for all patients with high risk was 79%.[269] For those who had responsive disease and therefore were eligible for randomization, the EFS was 90% for those receiving standard therapy and 80% for those receiving reduced intensity therapy. This difference led to the closure of the randomization and assignment of subsequent patients to the standard therapy arm. The NHL BFM95 evaluated the reduction of high-dose methotrexate-related toxicity by shortening the infusion time. Unlike in patients with lower risk where shorter infusion times had similar disease control but less toxicity, in patients with high risk changing the infusion time for the high-dose methotrexate from the standard 24 hours to only 4 hours resulted in an excess of tumor failures in patients with advanced disease.[484] The 3-year EFS rate for R3 and R4 groups (groups described in Table 53-15) overall were 85% and 81%, respectively. Combined, the R3 and R4 groups who received a shorter (4-hour) methotrexate infusion had an EFS rate of 77% versus 93% for those who received the longer (24-hour) infusion.

The group of patients with the worst outcome with current therapy is that of patients with CNS disease, defined by blasts in the CNS, cranial nerve palsies, or an intracranial mass. Among these patients the subgroup with the least favorable prognosis is those with blasts detectable in the CSF at the time of diagnosis, with EFS of 70% to 75% in FAB and BFM trials.[269,484]

Rituximab, the monoclonal chimeric anti-CD20 antibody, when added to conventional chemotherapy for adults with mature B-cell NHL, significantly improves outcomes.[485-487] For children and adolescents it is not part of standard therapy, primarily based on lack of evidence of efficacy in this patient group. Given the favorable outcome of children with conventional chemotherapy, the significant differences between chemotherapy regimens used in children and adults and the biologic difference in pediatric B-cell NHL, the adoption of the data from adult studies cannot be simply applied to pediatric care. Rituximab has shown to be active as a single agent when given upfront in a window trial before conventional therapy for children with B-cell NHL.[488] The COG has established the safety of combining rituximab with FAB-LMB96 therapy in a single-arm pilot trial of patients with high-risk disease.[489] The current international phase III trial for patients with high-risk B-cell NHL, InterB-NHL_2010_ritux will randomize patients to therapy based on the FAB backbone with or without rituximab to gather the needed data regarding efficacy.

Primary Central Nervous System DLBCL. Primary CNS NHL is exceptionally rare in children and adolescents. Most primary CNS NHLs of childhood are of the diffuse large B-cell subtype, though other histologies have been described.[265,490] In a large cohort of 2170 patients of the NHL-BFM studies, only 10 patients were observed with primary CNS lymphoma.[265] The estimated incidence in children in North America is 15 to 20 cases per year.[491] Most cases present with unifocal or multifocal intraparenchymal masses but some patients have meningeal disease only or combinations of both. The clinical features resemble those of brain tumors characterized by signs of increased intracranial pressure with headache, nausea and vomiting, and visual changes, as well as cranial nerve palsies, personality changes, and endocrinologic disturbances.

As with other rare tumors, optimal therapy in children and adolescents with primary CNS lymphoma is not clear. Treatment analogous to what patients who have CNS involvement as a component of more disseminated disease would receive has been effective in the BFM series.[265] The largest case series of pediatric patients with isolated CNS disease included 29 patients treated in various regimens with the majority receiving methotrexate-based regimens and one third receiving radiation in addition to chemotherapy. The 2-year OS rate was 82%.[492] The use of intrathecal rituximab combined with intrathecal methotrexate in adult patients with recurrent B-cell CNS lymphoma in a phase-I trial showed it to be feasible and active, although results have not been reported in children.[493]

Therapy of Relapsed Disease

Given the effectiveness of primary therapy, relapses are relatively rare. When they do occur, patients with BL generally relapse within 6 months from the time of completion of therapy. The period of risk is somewhat longer for those with DLBCL. Patients with primary refractory or relapsed B-cell NHL have a dismal prognosis. In a cohort of patients diagnosed with BL between 1977 and 1997, only 12% of those with relapsed disease survived.[494] There is no standard reinduction regimen for these patients. Commonly used regimens have included ICE as well as ifosfamide, etoposide and high-dose cytarabine.[416] A COG study evaluated the effectiveness of rituximab in addition to ICE therapy and showed a response rate of 60%. Six of the 20 patients were able to proceed in to

SCT. The OS rate at 3 years was 37%, with a majority of the survivors having received either an autologous or allogeneic SCT.[495] Retrospective data from the Center for International Blood and Marrow Transplant Research (CIBMTR) between 1990 and 2005 showed similar outcomes for both autologous and allogeneic SCT for patients with relapsed BL (31% and 27%, respectively) and DLCBL (50% and 52%, respectively).[411]

Anaplastic Large-Cell Lymphoma

ALCL accounts for 10% to 15 % of childhood NHL.[496] ALCL was first described by Stein and colleagues[18] in 1985, followed by the discovery of the nonrandom translocation of t(2:5) (p23; q35), causing the fusion of nucleophosmin (NPM) to the anaplastic lymphoma kinase (ALK) in a majority of the cases.[497,498] The disease has multiple features that are unlike other pediatric NHL subtypes, including the sites of involvement of disease at diagnosis and the responsiveness of relapsed disease to therapy as well as unique biologic features.

Pathologic Features

ALCL is characterized by large pleomorphic cells of a T/null immunophenotype. The morphology is variable but includes cells with eccentric horseshoe-shaped nuclei, called the *hallmark cells*.[39] A number of histologic variants have been described, including the common variant, characterized by sheets of large lymphoid cells; the lymphohistiocytic variant, characterized by a large number of reactive histiocytes that may even mask the anaplastic tumor cell population and can therefore be misdiagnosed as reactive histiocytic disease or malignant histiocytosis[40]; the small-cell variant, characterized by a predominant population of small to medium sized neoplastic cells with irregular nuclei[499,500]; and other rare variants including the giant cell variant, sarcomatoid variant, and neutrophil-rich variant. In some cases, mixtures of histologic subtypes are observed in one lesion, whereas in other patients different subtypes can be seen in different lesions.[500] In addition, in patients with relapsed disease the morphology of disease at relapse may be a different variant than was present at initial diagnosis.[501]

ALCL is CD30-positive on the cell membrane, particularly on large cells and in the Golgi region.[29] ALK detection is reliably measured by immunohistochemistry.[502] Cells express T-cell markers including CD2, CD5, and CD4, although the null-cell phenotype may not express several pan–T-cell antigens.[39]

ALK-negative ALCL is a unique disease category in the WHO classification. It is morphologically indistinguishable from the ALK-positive disease but lacks the expression of the ALK protein.[25] It accounts for less than 10% of pediatric disease and unlike in adult patients, has not been found to be associated with a worse prognosis in children.[273,274,500,503,504]

Molecular and Cellular Biology

The clonal nature of ALCL has been confirmed by the detection of the nonrandom chromosomal translocation t(2;5)(p23;q35) in malignant cells.[497,505,506] This translocation causes the *NPM* gene located at 5q35 to fuse with a gene at 2p23 encoding the receptor tyrosine kinase ALK.[498] The production of monoclonal antibodies directed against fixative-resistant epitopes of ALK allows its detection by immunohistochemistry.[507,508] Although the translocation t(2;5)(p23;q35) is the most common, more than 10 other chromosomal translocations juxtaposing the *ALK* gene at chromosome 2p23 to a partner gene have been detected. The partner gene of *ALK* determines the immunohistochemical ALK staining pattern. Only the NPM-ALK fusion protein is detectable in the cytoplasm and the nucleus because of the heterodimerization of the NPM portion with normal NPM, which functions in the nuclear shuttling of proteins.[509] All other fusion-gene products lacking the NPM portion are detectable only in the cytoplasm. Conversely, the ALK staining pattern, cytoplasmic and nuclear versus extranuclear, distinguishes the NPM-ALK translocation from all others.[510] In children, more than 90% of ALCL cases are ALK-positive.[273]

The cellular origin of ALCL is still not completely clarified. The vast majority express T-lineage antigens, have clonally rearranged *TCR* genes, and express the cytotoxic molecules perforin, granzyme B, and T-cell–restricted intracellular antigen (TIA) 1.[511] However, findings of plasmablastic B-cell lymphoma carrying the translocation t(2 ;5) and expressing NPM-ALK transcripts have suggested that the translocation involving ALK may not be restricted to ALCLs of T-cell lineage.[512] In a minority of cases, the expression of the natural killer (NK) cell–associated marker CD56 and the lack of detectable *TCR* gene rearrangements suggest an origination from NK cells rather than cytotoxic T cells.[511,513,514]

In most cases, ALCL occurs as a de novo malignant lymphoma. On rare occasions, however, ALCL appears as a secondary lymphoma that evolves from a low-grade or high-grade malignant T-cell lymphoma, Hodgkin lymphoma, or lymphomatoid papulosis.[515-518]

As mentioned, the most characteristic molecular feature of ALCL is the presence of gene rearrangements involving the *ALK* locus in chromosome band 2p23. ALK is a transmembrane receptor tyrosine kinase of the insulin receptor superfamily normally expressed only in cells of neural origin. ALCL translocations lead to the aberrant expression and constitutive activation of ALK.[519] The most common of these translocations present in 80% of ALCL cases is the t(2;5)(p23;q35).[520,521] In this translocation, the 5′ region of the *NPM* gene on chromosome 5q35 is fused to the *ALK* gene.[498,521-523] NPM is a ubiquitously expressed nucleolar phosphoprotein involved in the shuttling of ribonucleoproteins between the nucleus and cytoplasm.[524] The *NPM-ALK* fusion oncogene resulting from the t(2;5)(p23;q35) translocation encodes a constitutively active form of ALK,[521] which promotes cell transformation in vitro[509,525] and in vivo[526] by phosphorylating and activating important mediators in a number of critical signaling pathways such as PLCG, PI3K-AKT-mTOR, JAK2, STAT3, STAT5, and MEK-ERK.[519,522,527]

In addition to the t(2;5)(p23;q35) rearrangement, several other chromosomal translocations involving the *ALK* gene have been found in 20% of ALK-positive ALCL cases. All these rearrangements result in the fusion of the catalytic domain of ALK with different partners, such as tropomyosin *(TPM)* 3 and *TPM4, TGF, ATIC,* clathrin heavy chain, moesin, *AL017, TSPYL2, KIAA1618, VCL, KIFB5,* and *MYH9,*[519,527] and result in constitutively active ALK phosphorylation and activation.[521,528] All partners except *MYH9* provide dimerization domains, leading to the dimerization of the fusions and to the constitutive activation of the kinase.[528] The importance of the elucidation of constitutively active ALK as a major mechanism in the transformation of ALCL is highlighted by the development of specific ALK inhibitors. These may provide a targeted therapeutic strategy for treatment of this disease.[529]

In addition to ALK rearrangements, ALCLs also show other chromosomal alterations; however, few recurrent somatic lesions have been reported. About 25% of ALCLs display recurrent deletions affecting the 17p13.3-p12 region where the *TP53* gene is located, and 19% of cases show losses of 6q21 encompassing the *PRDM1* and *ATG5* genes.

Clinical Features

Most children and adolescents with ALCL have presenting symptoms of advanced stage disease. Almost all have lymphadenopathy at diagnosis, but 60% also have extranodal disease, most often involving soft tissue and skin followed by bone and lung.[274,503,504,530-532] Patients may have an indolent phase consisting of lymphadenopathy, which in some instances may be waxing and waning and sometimes associated with a history of illness including fever and other B symptoms.[516,533] Soft-tissue involvement may occur as multiple tumors in the subcutaneous tissue and muscles, or as a single larger tumor resembling a soft-tissue sarcoma. Bone manifestations vary from small osteolytic lesions to large tumors simulating bone tumors. Skin lesions may be single or multiple bluish-colored cutaneous or subcutaneous nodules, large ulcerated lesions or multiple or disseminated papillomatous lesions of a red-yellow color.

Compared with patients with BL or LL, the incidence of microscopically detectable bone-marrow disease at the time of diagnosis is lower. Occasionally, marked hemophagocytosis by macrophages can be observed in the bone marrow of patients with ALCL. In rare cases, disseminated intravascular coagulation of yet unknown pathogenesis has been observed as a paraneoplastic syndrome.[534] CNS disease is rare in patients with ALCL, affecting 1% to 4% of children.

Treatment and Outcomes

Prognostic Factors. Prognostic factors based on standard on clinical information used for informing treatment decisions have been less well-defined for patients with ALCL compared with other pediatric lymphomas. As with other NHLs, lower-stage disease is thought to be favorable. In the BFM90 study, nine patients with stage I and II resected disease had an EFS rate of 100% at 5 years with three courses of therapy.[274] A report including 36 patients with stage I disease on the ALCL99 study showed that those who had completely resected disease and received short-course chemotherapy also had an EFS rate of 100%, whereas those with incompletely resected disease had a relapse rate of 30%, similar to patients with higher-stage disease.[535]

A study that combined patients from three cooperative groups found that poor prognostic risk factors included disease involving the mediastinum, visceral involvement (lung, liver, or spleen), or skin lesions. Factors not significant in multivariate analysis included stage, B symptoms, and level of LDH.[536] In contrast to adults with ALCL, the *ALK1* positivity or negativity had no significant impact on outcome for children and adolescents.[273,274] However, this may be partly related to the relatively rarity of *ALK*-negative disease in children and therefore there is limited power to detect outcome differences.

Two specific tests, both unique to patients with *ALK*-positive ALCL and both done at the time of diagnosis, have been found to have prognostic significance in children with ALCL: the titer of anti-ALK antibodies in blood and copy number of *NPM-ALK* transcripts measured by quantitative PCR of bone marrow. Patients with *ALK*-positive ALCL often have measurable autoantibodies to ALK at the time of presentation with disease.[508] In a study of 95 uniformly treated pediatric patients with *ALK*-positive ALCL, an increased level of ALK autoantibodies in the patient's serum from the time of diagnosis correlated with a significantly lower incidence of relapse, suggesting that a preexisting immune response to the antigen product of the disease-specific translocation was protective from the risk of relapse.[537] Patients with morphologic involvement of their bone marrow make up a small proportion of those with ALCL. In a study of 80 pediatric patients with *ALK*-positive ALCL, only eight had morphologic evidence of bone-marrow involvement, but by assessing these samples with PCR, it was determined that 47.5% had detectable *NPM-ALK* transcript in these bone marrow samples. Using quantitative PCR it was found that those with a higher level of *NPM-ALK* transcript detection had a significantly higher rate of relapse.[538] When the two tests were combined from three patients groups treated in similar though not identical ways, three risk groups could be identified with dramatically different rates of progression survival. Twenty percent of patients had evidence of minimal disseminated disease as determined by PCR and had low or negative antibody titers. This high-risk group had a progression-free survival (PFS) rate of 28%. Conversely those who were negative for minimal disseminated disease and had high antibody titers, 31% of the patients, had a PFS rate of 93%. The intermediate-risk group, which included all others and accounted for 48% of the patients, had a PFS rate of 68%.[539] Replication of these findings and use in patient stratification are components of current and planned cooperative group trials.

Treatment. There is no consensus on optimal therapy for ALCL. Some groups have used brief intensive therapy, similar to that used for mature B-cell disease, whereas others have investigated more prolonged repeated pulse chemotherapy. EFS rates are very similar across studies even with the use of these variable chemotherapy regimens (Table 53-16).

TABLE 53-16 Prospective Randomized Trials of Childhood and Adolescent Anaplastic Large-Cell Lymphoma

Study Protocol (years)	No of Patients	Description of Therapy	Primary Study Question and Design	EFS at 3-5 Years	Primary Study Outcome
NHL-BFM90 (90-95)[274]	89	Short-pulse B NHL-type therapy: Stage I/II resected, 3 courses; Stage II non resected, stage III, 6 courses; Stage IV, 6 intensified courses; 2-5 months	Effectiveness of therapeutic regimen in nonselected group of uniformly treated patients, non randomized	76%	Short-pulse B NHL therapy is effective in ALCL.
POG (94-00)[530]	180	APO-based therapy for patients with large-cell lymphoma, both ALCL and DLBCL 12 months	Evaluation of intensified therapy with intermediate dose methotrexate and high-dose Ara-C, randomized between two regimens postinduction	71%	Intensification of therapy did not improve EFS and increased toxicity.
EICNHL (99-05)[504]	352	Short-pulse B NHL-type therapy; 5 months	Evaluation of modification of methotrexate dose and infusion time with or without intrathecal therapy, of efficacy of therapy with 3 g/m^2 over 3 hours versus 1 gm/m^2 over 24 hours	74% at 2 years	Methotrexate at 3 g/m^2 over 3 hours was as effective and less toxic than a lower dosage with prolonged infusion plus intrathecal therapy. Addition of vinblastine in maintenence delayed relapse but did not impact 2-yr EFS.
ALCL99 (99-06)[503]	110	Short-pulse B NHL-type therapy; 5 months	Evaluation of addition of vinblastine in maintenence versus no maintenence	70%-73% at 2 years	Addition of vinblastine in maintanence delayed relapse but did not impact 2-yr EFS.
COG[542]	125	APO-based therapy; 12 months	Evaluation of vincristine versus vinblastine in postinduction	76% at 3 years	No benefit was found with the use of vinblastine compared with vincristine; vinblastine administration was limited by myelotoxicity.

ALCL, Anaplastic large-cell lymphoma; *APO,* doxorubicin, vincristine, prednisone, 6-mercaptopurine, and low-dose methotrexate; *Ara-C,* cytarabine; *COG,* Children's Oncology Group; *DLBCL,* diffuse large B-cell lymphoma; *EFS,* event-free survival; *EICNHL,* European Intergroup for Childhood Non-Hodgkin Lymphoma; *NHL,* non-Hodgkin lymphoma; *NHL-BFM,* Non-Hodgkin Lymphoma–Berlin-Frankfurt-Munster; *POG,* Pediatric Oncology Group.

Analysis of patients from three consecutive BFM trials showed that the use of B-cell NHL short-pulse therapy was effective for the ALCL group, with a 5-year EFS rate of 76%.[540] In the BFM90 trial, 89 patients with ALCL were treated. In this trial patients were divided into three groups based on stage: K1, stage I and II resected; K2, stage II nonresected and stage III; and K3, stage IV or those with multifocal bone involvement. All groups received a prephase treatment and then 3 to 6 cycles of therapy lasting 2 to 5 months, with the K3 group's therapy intensified primarily by higher dose methotrexate. With this regimen the OS rate at 5 years for the whole group was again 76%.[274] Of the patients that did relapse, the vast majority did so within 15 months of the completion of therapy. Relapses occurred at both original and new sites.

After the BFM90 trial, a large randomized study, ALCL99, was conducted by the European Intergroup for Childhood Non-Hodgkin Lymphoma (EICNHL) and designed to address two questions in patients with ALCL. The first task was to assess the safety and efficacy of two methotrexate regimens (3 g/m^2 over 3 hours with no intrathecal therapy versus 1 g/m^2 over 24 hours with intrathecal therapy). The 2-year EFS rate was identical in the two arms at 74%, although the shorter high-dose methotrexate arm was associated with less toxicity. There was no difference in CNS relapses. Again in this trial it was noted that almost all of the relapses occurred within 2 years from completion of therapy.[503]

The second question addressed in ALCL99 included only the high-risk patients, defined as those with mediastinal, lung, liver, spleen, or skin involvement. Eligible patients were randomized to receive vinblastine concurrent with intensive therapy and as a single-drug maintenance regimen for a total duration of therapy of 1 year versus the standard backbone therapy and no maintenance.[503] At 1 year from the time of randomization the EFS rate for those receiving vinblastine was superior (91% versus 74%), but by 2 years the difference was no longer present with an EFS rate of 73% and 70% respectively. The conclusion was that vinblastine delivered in this manner delayed recurrences but did not impact the overall outcome.[503]

In North America POG performed a series of clinical trials evaluating modifications of the APO therapy backbone.[530,541] APO therapy involves the use of doxorubicin, prednisone, and vincristine in addition to 6-mercaptopurine, low dose methotrextae and intrathecal therapy given as multiple cycles over 2 years in the outpatient setting. This therapy includes a cumulative anthracycline dose of 300 mg/m^2. Patients in these earlier studies included those with advanced-stage disease and with both DLBCL and T-cell phenotype large-cell lymphoma. In these studies, neither intensifying therapy with cyclophosphamide or with intermediate-dose methotrexate and high-dose cytarabine had an impact of EFS, with no statistical difference in outcome between randomized arms in either study. The 4-year EFS rate for the subgroup of ALCL patients, irrespective of randomized therapy, was 71%.[530] Analogous to the pattern in the European trails, the majority of relapses occurred within 2 years of diagnosis.

Subsequent to these studies and analogous to the ALCL99 trial, the COG investigated the impact of vinblastine in the context of APO therapy. In the trial, patients were randomized between treatment with vincristine or vinblastine as part of multiagent maintenance therapy based on the APO backbone. No benefit was found with the use of vinblastine compared with vincristine, although the ability to administer the vinblastine at the originally planned doses was hampered by cytopenias.[542]

The incidence of CNS relapse in patients who are initially CNS-negative is very low, with therapy protocols that involve corticosteroids and systemic methotrexate therapy with or without intrathecal therapy.[265,273,274,516] Prophylactic cranial irradiation is unnecessary. In the European intergroup trial ALCL99 based on the treatment strategy of the NHL-BFM90 study, including dexamethasone as a corticosteroid, it was shown that systemic methotrexate, 3 g/m^2, given as an IV infusion for 3 hours, is sufficient CNS protection for patients without overt CNS disease at diagnosis, and additional intrathecal chemotherapy is not necessary.[534] Because of the small numbers of patients with overt CNS disease at diagnosis, no conclusions can be drawn about optimal treatment in this circumstance. Therapeutic cranial irradiation with doses of 18 to 24 Gy, depending on age, may be efficacious in addition to high-dose methotrexate and high-dose cytarabine combined with triple-drug intrathecal therapy.[273,274]

Treatment of Relapsed Anaplastic Large-Cell Lymphoma

One of the unique features of ALCL compared with other pediatric NHLs is its sensitivity to chemotherapy after recurrence. Of particular interest is the experience of maintenance of prolonged second remissions with single-agent vinblastine. A report of 41 children with relapsed disease enrolled in three consecutive French Society of Pediatric Oncology trials described outcomes with various second-line therapies.[543] Thirty-six of 41 patients (88%) were able to achieve a second complete response. The overall and disease-free survival rates were 69% and 44%, respectively, at 3 years. In this series it was noted that eight of 13 patients had long-lasting remissions with single-agent vinblastine therapy alone. A second report described the experience with 30 patients treated with single-agent vinblastine most commonly given at a dose of 6 mg/m^2 weekly, for varying durations, at varying time points in the patient's disease course, although the majority were treated for first of second relapse.[504] Fifty percent of the patients had a preceding SCT before their vinblastine therapy. The CR rate for the whole group was 83%. The 5-year EFS and OS rates for the whole group were 30% and 65%. Of note, 30% of those treated with vinblastine only remained in CR.

ALCL is characterized in part by its expression of CD30. Monoclonal antibody therapy directed at CD30 has shown to be safe but with limited activity in early phase studies in adult patients.[544] Brentuximab vedotin (SGN-35) is an antibody drug conjugate combing an anti-CD30 antibody with a potent microtubule inhibitor, monomethylauristatin E (MMAE). A phase-II study in adult patients with primary refractory or relapsed ALK-positive or ALK-negative ALCL showed very encouraging results.[545] Eighty-six percent (50/58) of heavily pretreated patients had a response to therapy, and 57% obtained complete response to monotherapy with brentuximab vedotin. Toxicity was modest, including cytopenias and peripheral neuropathy. Studies evaluating the safety and efficacy of this agent in children and in combination with conventional chemotherapies as part of initial therapy and therapy for relapsed disease for patients with both Hodgkin lymphoma and ALCL are being undertaken.

Another extremely exciting agent for the treatment of children and adolescents with ALK-positive ALCL is crizotinib, a small-molecule inhibitor of ALK tyrosine kinase. Two adult patients with refractory ALK-positive ALCL were able to obtain a complete response with crizotinib.[546] In the pediatric setting it is being investigated in early-phase studies for patients with ALK-positive disease including ALCL and neuroblastoma.[547] Given the early indications of safety of the drug and of efficacy in patients with ALCL, plans for evaluating crizotinib in conjunction with standard chemotherapy in newly diagnosed patients are being pursued by the COG.[232]

Rare Lymphomas in Children and Adolescents

LL, mature B-cell lymphomas, and ALCL account for the vast majority of NHLs diagnosed in children and adolescents; however approximately 10% of cases are made up of an array of much rarer entities, some of which are much more commonly seen in adults. A discussion of some of these rare tumors is included below.

Primary Mediastinal (Thymic) Large B-Cell Lymphoma

Primary mediastinal (thymic) large B-cell lymphoma (PMBCL) is a DLBCL with unique clinical, histologic, and genetic characteristics that have justified its being identified as a unique entity in the WHO classification system for lymphomas.[39] Microscopically a prominent compartmentalizing sclerosis dominates the histologic appearance. The malignant cells are of putative thymic B-cell origin and are large, often pleomorphic, lymphoid cells with abundant pale cytoplasm. The cells express CD45 and B-lineage markers such as CD19, CD20, and CD79a, but surface immunoglobulin is usually absent. Contrary to DLBCL, PMLBL cells do not express CD10 or *BCL6* and *BCL2*.[548] The neoplastic cells may express CD30, although usually less strongly than in Hodgkin lymphoma.

PMBCL usually presents with symptoms emanating from the effects of a large mediastinal mass such as cough, shortness of breath, and signs and symptoms of SVC syndrome. The tumor generally spreads locally with invasion into the pleura, pericardium, and lungs but may also involve the liver.[549] Bone-marrow and CNS involvement is exceptionally rare.[550]

The prognosis for pediatric patients with PMBCL has been less favorable than for the other mature B-cell lymphomas. Multiple pediatric international cooperative group studies have reported remarkably consistent outcome data with a 5-year EFS rate of 66% to 67% and an OS rate of 73% to 79%.[551,552] The best results reported to date are from a case series of adult patients treated with rituximab in addition to the combination chemotherapy regime of dose-adjusted etoposide, prednisone, vincristine (Oncovin), cyclophosphamide, and doxorubicin (hydroxydaunorubicin) (EPOCH).[553] The importance of radiotherapy in this group of patients is controversial, with some adult studies reporting improved outcome with IFRT, whereas its impact on patient outcomes in the combined pediatric data showed no advantage.[551,554] The international pediatric B-cell study (interB NHL-ritux-2010) will evaluate the use of dose-adjusted EPOCH with rituximab in a single-arm phase-II component of the larger trial.

Juvenile Follicular Lymphoma

FL is a common diagnosis in adults with NHL but is very rare in children, accounting for fewer than 2% of all pediatric cases. In the 2008 WHO classification of lymphomas, pediatric FL is identified as a unique entity based on patient age but also on the unique biologic features including lack of *BCL2* expression and absence of t(14:18) in the majority of cases.[39] Pediatric FL tends to be of higher grade than its adult counterpart.[555] Children with FL generally have a presentation of low-stage disease, most often involving cervical nodes, other peripheral nodes, Waldeyer ring, or isolated testicular disease. The outcome for children with FL is very favorable including a small number of patients successfully treated with surgical resection alone, although the majority of patients have been treated with brief courses of multiagent chemotherapy.[556-558] Unlike in adult patients, the use of rituximab in the treatment of pediatric FL has not been investigated.[559]

Peripheral T-Cell Lymphomas

Peripheral T-cell lymphomas (PTCLs) other than ALCLs are rare in childhood and account for fewer than 1% of cases. They represent a heterogeneous group of neoplasms, with the most common histology among pediatric patients being PTCL, not otherwise specified. The clinical features, histology, and genetic features are variable by subtype.[39]

Data in children and adolescents with non-ALCL PTCL are limited to several case series and a number of case reports but suggest that the outcome of these patients is inferior compared with that of the more common pediatric NHL histologies.[560-563] Patients with lower-stage disease have a more favorable outcome, although the majority of patients have presenting symptoms of advanced stage disease. The optimal therapy for patients with non-ALCL PTCL is unclear, with some groups suggesting B-cell NHL–type therapy and others T-cell leukemia/lymphoma–like therapy, and with some data supporting specific therapies based on specific histology. In addition, the role of high-dose therapy and autologous or allogeneic transplant in the management of pediatric patients remain unclear.

Late Effects of Therapy

In contrast to pediatric Hodgkin lymphoma, few reports are available on late effects in long-term survivors of childhood and adolescent NHL. The risk of second cancer for survivors of childhood and adolescent NHL appears to be much lower compared with patients with Hodgkin lymphoma. In the CCSS, the excess risk for second cancers was among the lowest for children treated for NHL as compared with all other malignancies, with a cumulative risk for SMN of 1.9% after 20 years.[202,564] However, only events occurring 5 years or later from diagnosis of NHL were included in that analysis, and therefore secondary AML, which usually has a short latency, may have been underestimated in that study. In a single-center study of 497 former pediatric NHL patients, AML was reported to be the most common second malignancy.[565] In that study, the cumulative incidences of SMN at 10 and 20 years were 2.1% and 4.8%, respectively. Seven of 16 SMNs observed were AML with exposure to epipodophyllotoxins a significant risk factor. Another analysis of 103 patients treated as children for NHL, major late effects observed were cardiac toxicity and hepatitis C virus (HCV) infection, the latter presumably resulting from blood transfusions before HCV screening was introduced.[566] Cardiotoxicity was observed in patients who received anthracycline doses of more than 400 mg/m^2. Fertility was not greatly impaired. In long-term survivors of pediatric NHL, the risk for limitations on physical performance and daily activities was among the lowest compared with survivors of other childhood cancers, although higher compared with healthy siblings.[567]

POSTTRANSPLANTATION LYMPHOPROLIFERATIVE DISEASE

Lymphoproliferative disorders are the most common malignancies in children and adolescents with iatrogenic impaired immune function after solid-organ transplantation (SOT) or allogeneic hematopoietic SCT.[568]

Posttransplantation lymphoproliferative disease (PTLD) represents a spectrum of clinically, morphologically, and biologically heterogeneous disorders defined as any lymphoid proliferation or lymphoma developing as a consequence of pharmacologic immunosuppression after SOT or hematopoietic SCT. The initial clinical presentation is extraordinarily broad, ranging from a single, small, asymptomatic lymphomatous tumor, an infectious mononucleosis-like syndrome, and unexplained fever to a widespread disseminated disease with a rapid fatal course. Any organ can be involved by interstitial infiltration of lymphocytes or tumorous lesions, including meninges and the CNS. Occasional spontaneous regression is observed and may be a feature intrinsic to the nature of the disorder as a result of a disturbed balance of immune surveillance. Especially in patients who have had hematopoietic SCT, PTLD may even go unrecognized until autopsy because of the lack of localized tumors and may be clinically misdiagnosed for graft-versus-host disease (GVHD) or infection.[569] In post-SOT PTLD, the malignant cells are almost invariably of recipient origin, whereas in postallogeneic SCT the cell of origin is more commonly of donor origin.

Classification and Epidemiology

According to the WHO classification of hematologic malignancies, PTLD is divided into four subtypes: early lesions, polymorphic PTLD, monomorphic PTLD (classified according to the lymphomas they resemble), and classic Hodgkin lymphoma–type PTLD (Box 53-3).[26,39] In the vast majority of cases, PTLD cells are of B-cell lineage, with a wide spectrum of phenotypes.[570] The B-lineage antigen CD20 is expressed in most cases but not all.[571] In rare cases a T-cell phenotype of PTLD is observed.[572] PTLD can be polyclonal, oligoclonal, or monoclonal, and polymorphic and monomorphic lesions can be observed concurrently in the same patient.[573] Of post-SOT PTLD cases, 70% to 80% are associated with EBV, whereas almost all posthematopoietic SCT PTLD cases are EBV-positive.[26]

CLASSIC HODGKIN LYMPHOMA–TYPE POSTTRANSPLANTATION LYMPHOPROLIFERATIVE DISEASE

Modified from Swerdlow SH, Campo E, Harris NL et al: WHO classification of tumours of haematopoietic and lymphoid tissues, *IARC Press, 2008, Lyon.*

The incidence of PTLD in post-SOT varies widely. The two most significant risk factors for PTLD are the organ recipient being EBV-negative at the time of transplant and the degree of immunosuppression.[574] Degree of immunosuppression varies with type of SOT, and consequently risks of PTLD vary with organ type, with the incidence highest in patients who have had heart-lung or intestinal transplants, intermediate for those who have had heart or liver transplants, and lowest for patients after kidney transplant. Children have a higher incidence than adults, explained in part by the increased rate of EBV negativity at the time of organ transplant. Risk of PTLD after allogeneic SCT is increased in those with a T-cell–depleted stem-cell source and in patients whose conditioning regimen included antithymocyte globulin.

Treatment and Outcomes

Preemptive strategies for PTLD in patients with SOT have had mixed results. In contrast to cytomegalovirus (CMV), the prophylactic or preemptive use of antiviral drugs such as acyclovir or ganciclovir appears not to be efficacious to prevent EBV-related disease in transplant recipients.[575] Serial quantitative measurements of EBV DNA by real-time PCR in the blood of patients receiving transplants is a sensitive but not specific marker for the risk of development of PTLD.[576-580] The combined testing for EBV viral load and the amount of EBV-specific T cells that are CD8- and/or CD4-positive in transplant recipients increases significantly the accuracy to predict the risk of PTLD.[581,582] The use of preemptive rituximab may prove to be of benefit.[583]

The mortality of PTLD remains high with survival at 2 years ranging between 54% and 89%,[584-587] with deaths attributed both to progressive disease as well as to graft loss. Principles of therapy include early recognition, risk stratification for therapeutic decisions, and considerations for restoring host immunocompetence.

Reduction of immunosuppression (RIS) should be considered in all newly diagnosed patients. The success of RIS varies widely with increased likelihood of response found in those patients with polymorphic histology, localized nonbulky disease, and a normal LDH.[588-590] Patients with localized disease who undergo complete surgical excision and tolerate RIS have a very good outcome.[588,590] The average time to response has been reported as 3 weeks.[589] For patients with monomorphic or disseminated disease as well as those for whom RIS is initiated but then show evidence of progressive disease or organ rejection, additional interventions need to be undertaken. The utility of RIS in PTLD posthematopoietic SCT is unknown.

Monotherapy with the anti-CD20 agent rituximab has been investigated in patients who are unresponsive to RIS or with recurrent disease. Response rates range from 44% to 85% percent with approximately 2 out of 3 of patients having durable responses.[591,592] A single study of patients with posthematopoietic SCT PTLD strongly favored rituximab, with none of those who did not receive it alive at day 180 versus 46% of those who did.[593] A strategy of "risk-stratified sequential approach" with the use of rituximab and RIS for 4 weeks. Those achieving CR had an additional 4 weeks of rituximab, and those with less than a CR received to rituximab plus cyclophosphamide, doxorubicin (hydroxydaunorubicin), vincristine (Oncovin) and prednisone (CHOP) chemotherapy. All had excellent outcomes with a 1-year progression free survival rate of 93%.[594]

Therapy with low-dose chemotherapy regimens have been investigated using cyclophosphamide and prednisone with or without rituximab with evidence of durable responses in approximately 70% of patients.[595,596] Patients with fulminant PTLD, defined as those with fever, hypotension, and disseminated disease, have a worse prognosis that may be improved by the addition of rituximab to low-dose regimens.[596]

Standard intensive lymphoma therapy should be considered for patients who are unresponsive to low-dose regimens, have EBV-negative PTLD, and for those with Burkitt pathology.[597] Patients with CNS involvement of their PTLD have significantly inferior survival rates. For these patients the addition of high-dose methotrexate should be considered. Responses to intrathecal rituximab have been reported.[598,599] The optimal treatment for the rare patient with T-cell PTLD is unknown, although regimens similar to those used for T-cell ALL have been used.

There is no standard therapy for patients with PTLD after SCT. A number of reports have described the efficacy of rituximab in this setting.[591,600,601] Others have reported responses to donor lymphocyte infusions.[602,603] The adoptive transfer of EBV-specific T-effector cells offers a promising option to treat and or even prevent PTLD.[604]

CONCLUSION AND FUTURE DIRECTIONS IN PEDIATRIC LYMPHOMA

Insights into the pathogenesis and cellular biology have dramatically improved, as have the outcomes for children and adolescents treated for lymphoma. Widely accepted classification systems have allowed for clearer description and comparison of data between investigators. Nevertheless, important issues remain. Knowledge of causative factors is still limited. Although lymphomas were among the first human malignancies for which an infectious cause was hypothesized, definitive clarification of the role of infectious agents in the pathogenesis of childhood lymphoma is still evolving. BL and Hodgkin lymphoma, as well as PTLD, are all associated with EBV and account for a considerable proportion of childhood malignancies worldwide. Thus the clarification of an interaction of genetic predisposition and infectious agents in their pathogenesis merits ongoing efforts. For those lymphomas where curative therapy is now the expectation, investigations into reduction of the treatment burden while maintaining efficacy are warranted. In addition, exploration of new treatment options based on more refined understanding of biology and the availability of targeted therapy such as ALK inhibitors or novel monoclonal antibodies has the potential to change the nature of lymphoma therapy. Refining prognostic indicators such as kinetics of disease response by functional imaging or measurement of minimal disseminated and residual disease may allow for more informed decisions regarding treatment intensity. The outcome of children and adolescents with lymphoma has changed dramatically in the past 50 years. The hope and expectation is that progress will continue in the basic scientific understanding and in its translation to clinical care to continue to improve the outlook for these patients.

CONCLUSIONS AND FUTURE DIRECTIONS

Neuroblastoma is an embryonal tumor of the sympathetic nervous system arising from the neural crest. It is a common extracranial solid tumor of childhood and is a disease distinguished by its clinical and biologic heterogeneity. The prognosis for persons with neuroblastoma is variable and largely dependent on tumor biology. Patients with localized disease and favorable tumor biology may be successfully treated with surgery alone or with minimal therapy with an estimated 5-year survival rate of 90%.[1] However approximately half of all patients present with metastatic disease, adverse tumor-specific biologic features, or both. For these children with "high-risk" disease features, cure rates remain poor, with estimated 5-year survival rates of 50%.[1] The development of resistance to chemotherapy and radiation is the cause of most treatment failures, and neuroblastoma accounts for 10% of childhood cancer mortality. This chapter summarizes our current understanding of neuroblastoma biology and pathogenesis and how this rapidly evolving insight has affected current and future treatment strategies.

EPIDEMIOLOGY

Neuroblastoma accounts for 7% of all childhood cancer diagnoses, with more than 650 new cases diagnosed in the United States each year.[2] The incidence of neuroblastoma is 10.5 per million children younger than 15 years of age per year.[2] It is the most commonly diagnosed cancer of infancy.[2] The median age of diagnosis is 19 months, with a peak incidence in children younger than 4 years.[3] There is no racial preponderance, although African Americans are more likely to have high-risk disease and a fatal outcome.[4,5] Large-scale genetic studies to investigate how this likelihood may influence the disease phenotype revealed that a single nucleotide polymorphism (SNP) within the sperm-associated antigen 16 *(SPAG16)* gene had a higher risk allele frequency in the African reference population and contributed to the ethnic disparities in high-risk disease and survival.[6]

The cause of neuroblastoma is largely unknown. The embryonal origin of the tumor, as well as the young age of onset, suggest that prenatal and perinatal exposures may be important. Studies have investigated a variety of prenatal exposures including tobacco, alcohol, pesticides, and maternal medication or drug use, as well as birth characteristics, including small size for gestational age and maternal history of fetal loss.[7-10,11] The findings from these studies have been inconsistent, and none of these associations has been confirmed in large studies.

Because the majority of neuroblastomas produce catecholamine metabolites that can be detected in the urine, infant screening programs have been conducted to see if it is possible to decrease the mortality from high-risk neuroblastoma by diagnosing cases earlier. In Japan, starting in 1985, a nationwide mass screening program for neuroblastoma was conducted in 6-month-old infants. Results showed that the incidence rate of neuroblastoma increased two- to threefold as a result of the screening, implying that without screening, many of these tumors would have regressed spontaneously and would never have been diagnosed clinically. In addition, the majority of patients had low-stage disease and biologically favorable features, and screening did not decrease overall neuroblastoma mortality.[12-17] Through the Quebec Neuroblastoma Screening Program, infants were screened at 3 weeks and 6 months; the findings confirmed the Japanese results[18,19] and showed a significant complication rate in patients undergoing treatment for tumors found by screening.[20] In the German Neuroblastoma Screening Study, investigators looked at postponing screening until 10 to 19 months of age.[21,22] They found less "overdiagnosis" of neuroblastoma and a greater frequency of patients with unfavorable clinical and biologic features. However, no decrease in the mortality of the patients with unfavorable features was documented. Because of these results, mass screening efforts for neuroblastoma in infants have largely been abandoned.

PATHOGENESIS

Embryology

Neuroblastoma arises during development from neural crest cells committed to the sympathoadrenal lineage.[23,24] The two predominant cell types comprising neuroblastoma are neuroblasts and Schwann cells. Neuroblasts derive from pluripotent cells that arise in the neural crest and eventually form various components of the sympathetic nervous system: the sympathetic ganglia, the chromaffin cells of the adrenal medulla, and the paraganglia, which are typical sites where neuroblastic tumors can arise. What causes persistence of these embryonal cells that develop into peripheral neuroblastic tumors is unclear. Genes that dictate neural development could be altered, causing defects in the normal differentiation and programmed cell death pathways, leading to uncontrolled proliferation and aberrant cell survival.

Microscopic neuroblastic nodules have been reported in fetal adrenal glands during development, peaking at around 17 to 20 weeks' gestation and regressing by birth or within the first few months of postnatal life.[25,26] Beckwith and Perrin[27] (1963) termed these nodules, which were histologically identical to neuroblastoma, "neuroblastoma in situ," which they noted during postmortem examinations of infants younger than 3 months of age who died of other causes. These lesions were detected with a frequency fiftyfold higher than the expected incidence of primary adrenal neuroblastoma and were initially thought to be neuroblastomas that regressed spontaneously. However, with new insights into the development of the adrenal gland, it is clear that these are remnants from normal fetal development.[27] Indeed, the genetic profiles of normal developing neuroblasts and malignant neuroblastomas are similar in many respects, as shown by messenger ribonucleic acid (mRNA) expression profiling of sympathetic neuroblasts from human fetal adrenal glands.[28]

Development of the Sympathetic Nervous System

The sympathetic nervous system is derived from the neural crest, a multipotent embryonic structure that appears early in development and is made up of a transient population of cells that migrate from the neural tube to the region of the dorsal aorta during development.[29-31] These cells develop into sympathetic, parasympathetic, enteric, or sensory neurons governed by transcriptional regulators and growth factors as they exit from the neural tube, during migration or at sites where these cells differentiate. Development of the sympathetic phenotype is summarized in Figure 54-1.[32] Premigratory neural crest cells are specified by the expression of several markers, including FoxD3 and SOX10. *Foxd3* is required for sublineage fate specification, migration, and survival. Zebrafish homozygous for *foxd3* inactivating mutations have nearly a complete loss of sympathetic neurons and their precursor populations.[33] *Sox10* is responsible for the multipotency of neural crest–derived cells and is required for sympathetic nervous system and melanocyte development.[34] At the dorsal aorta, prespecified *SOX10*-positive sympathetic progenitors that are under the influence of extrinsic factors, bone morphogenetic proteins, start the process of differentiation into noradrenergic neurons.[35] The basic helix-loop-helix (bHLH) transcription factor *Ascl1* and the homeodomain transcription factor *Phox2b* are the first transcription factors that are expressed upon initiation of differentiation of sympathoadrenal precursors.[36-40] *Phox2a*, a homolog of *PHOX2B*, is expressed downstream of both *Phoxb* and *Ascl1*,[36,40,41] but its role in the initial stages of the sympathetic lineage remains undefined. Further neuronal differentiation occurs under the influence of the transcription factors *Hand2*,[42,43] *Gata2/3*,[44] and *Tfap2a*,[45,46] which interact in a complex regulatory network to ultimately induce the expression of tyrosine hydroxylase (TH) and dopamine beta hydroxylase. These two enzymes are required for

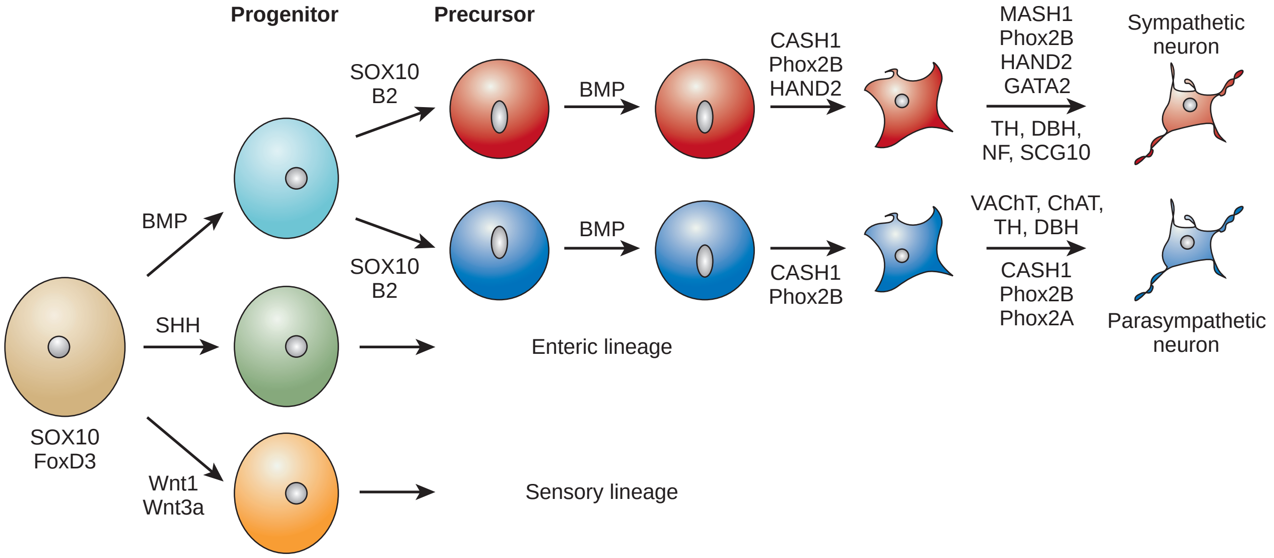

Figure 54-1 The development of the autonomic nervous system. A series of growth factors and transcriptional regulators affect different stages of neurogenesis of neural crest–derived progenitor cells. Neural crest cells segregated from the neuroepithelium can be identified by the expression of forkhead box D3 *(FoxD3)* and sex-determining region Y box–10 *(SOX10)*, among other markers. Progenitor cells differentiate into sympathetic, parasympathetic, enteric, or sensory neurons that are in part dependent upon instructive signals encountered early at or near the time of egress from the neural tube. Additionally, extrinsic cues encountered during migration or at sites where neural crest–derived cells differentiate influence patterns of gene expression. *(Modified from Howard MJ. Mechanisms and perspectives on differentiation of autonomic neurons.* Dev Biol *277:271–286, 2005.)*

catecholamine production and serve as markers of terminal sympathetic neuronal differentiation.[47,48] *Hand2* appears to have more of a role in noradrenergic cell proliferation than differentiation. A massive reduction in sympathetic ganglion size occurs after elimination of Hand2 in the neural crest of model organisms because of a nearly complete block in proliferation of immature sympathetic neurons.[49] Thus different members of the gene regulatory network appear to have selective functions, some in proliferation and others in differentiation.[30]

Neural crest cells from the cranial region migrate from the neural folds into the pharyngeal arches and heart, where they play essential roles in septation of the single outflow of the heart (the truncus arteriosus) and in the formation of the conotruncal portion of the ventricular septum.[50] It follows that coexistence of neuroblastoma with anomalies of other neural crest–derived structures is biologically plausible because of the shared roles of regulatory and developmental genes. For example, ablation of the cardiac neural crest results in congenital cardiovascular malformations in the chick embryo.[50] Indeed, a significantly increased incidence of congenital cardiac malformations, especially those that involve neural crest–derived tissues, was noted in patients with neuroblastoma compared with other malignancies, such as leukemia.[51] These cardiac anomalies were seen primarily in patients with neuroblastoma who were younger than 1 year and had lower stage tumors. Menegaux et al.[52] (2005) confirmed the association of neuroblastoma with conotruncal cardiac anomalies, as well as with various urogenital anomalies; other studies have shown varying results.[53-55] Although the malignant transformation of neuroblasts and the disruption of normal cardiogenesis are likely to be multistep processes, it is possible that shared initiating genetic lesions occur very early in development, causing derangement of common developmental pathways.

Genetic Disorders Associated with Neuroblastoma

Neuroblastoma may occur rarely in association with chromosomal anomalies. In addition to the increased incidence of neuroblastoma in girls with Turner syndrome,[56] neuroblastoma has also been noted to occur in patients with Noonan syndrome.[57] The gene encoding the protein phosphatase PTPN11 is mutated in 50% of patients with Noonan syndrome and is associated with an increased risk of leukemia[58] and neuroblastoma.[57,59] Other neuro-cardio-facial syndromes such as Costello syndrome have been associated with neuroblastic tumors. Mutations in the neurofibromatosis type 1 *(NF1)* gene have been detected in neuroblastoma cell lines,[60,61] and the literature includes one case report of a patient with a germline *NF1* mutation and neuroblastoma who had a homozygous deletion of the *NF1* gene in the tumor.[62] However, germline inactivation of *Nf1* does not predispose to neuroblastoma in the mouse.

Persons affected with overgrowth disorders such as Beckwith-Weidemann syndrome are at risk for embryonal tumors, including neuroblastoma. The increased risk is mainly during the first 4 years of life, and current recommendations include quarterly evaluation with abdominal ultrasound until age 8 years.[63] The molecular aberrations that predispose to neuroblastoma in particular are unknown, although maternal differentially methylated region 2 (DMR2) loss of methylation that occurs in 50% to 60% of cases is thought to confer a 1% to 5%

risk of developing non–Wilm tumors, including neuroblastoma, hepatoblastoma, rhabdomyosarcoma, adrenocortical tumors, gonadoblastoma, and thyroid carcinoma. Mutations of the *CDKN1C* tumor suppressor gene (encoding the cyclin-dependent kinase inhibitor $p57^{KIP2}$), which occur in 5% to 10% of sporadic and 30% to 50% of familial cases, is associated with a 4% estimated risk of non–Wilm tumor formation.[63,64] The X-linked Simpson-Golabi-Behmel syndrome type 1 (SGBS1), associated with mutations in glypican 3 and 4 *(GPC3* and *GPC4)* genes, is characterized by prenatal and postnatal macrosomia, distinctive craniofacies with palatal anomalies, congenital heart defects, and neuroblastoma (reviewed in reference 65). Surveillance is recommended for embryonal tumors starting in the newborn period.[65]

Neuroblastoma Stem Cells

The natural course of high-risk neuroblastoma, which results in relapse and a refractory state after an initial good response, suggests the likely existence of cancer stem cells (CSCs) in these tumors. CSCs are a subpopulation of cells within a tumor with the ability to self-renew, generate differentiated progeny, and reproduce a heterogeneous cancer population.[66] These cells have enhanced tumorigenicity, resistance to chemotherapy, and the ability to establish metastatic foci. Hansford et al.[67] (2007) demonstrated that dissociated cells from neuroblastoma tumors and bone marrow metastases grow as spheres and are capable of self-renewal. Spheres generated from the tumors underwent differentiation under neurogenic conditions to form neurons. Neuroblastoma stem cells from high-risk tumors expressed markers of neural crest stem cells and clinical markers of neuroblastoma, exhibited a higher self-renewal rate than those from low-risk tumors, and formed metastatic tumors that could be serially passaged in xenograft models.[67] Compounds that selectively targeted these tumor-initiating cells (TICs)—DEC14 and rapamycin—were identified; they induced regression of TIC tumor models in vivo and markedly decreased self-renewal or tumor initiation capacity.[68] Moreover, compounds that targeted PI3K/Akt, PKC, aurora kinase, ErbB2, Trk, and polo-like kinase–1 (PLK1) emerged from a small molecule inhibitor library screen designed to identify signaling pathways important for the survival and self-renewal of neuroblastoma TICs. Genetic and chemical inhibition of PLK1 caused regression of TIC tumor models both singly and in combination with irinotecan, suggesting that this kinase may regulate TIC growth and survival.[69]

Cluster of differentiation (CD)–133, in addition to being a marker of hematopoietic stem cells, is also a marker of TICs in several human cancers. CD133-positive subpopulations of cells with tumor-initiating and metastatic properties have been identified in neuroblastoma tumors.[70] Similarly, the stemness-related polycomb repressive complex–1 (PRC1) protein BMI1 is thought to have a role in tumor sphere formation. BMI1 is thought to inhibit neuroblastoma differentiation by repressing expression of the tumor suppressor in lung cancer–1 (TSLC1) and kinesin family member 1B (KIF1B) in these cells.[71]

In a 2013 study,[72] surface expression of the granulocyte colony-stimulating factor receptor CD114 was found to distinguish a subpopulation of neuroblastoma cells in cell lines and primary tumors, the proportion of which was increased in relapsed tumors. These cells were found to have increased responsiveness to signal transducer and activator of transcription–3 (STAT3), a critical transcription factor controlling neural crest specification. This subpopulation of cells was highly tumorigenic, could self-renew, and could give rise to differentiated progeny with characteristics of premigratory neural crest cells. This subpopulation possessed an undifferentiated phenotype similar to that found in early multipotent neural crest precursors.[72] Further studies are required to understand the role of CSCs in neuroblastoma.

Hereditary Predisposition to Neuroblastoma

A family history has been identified in 1% of cases of neuroblastoma and is suggestive of autosomal-dominant inheritance.[73] In these children, neuroblastoma develops at an earlier age and often manifests as multiple primary tumors.

PHOX2B Mutations

The first predisposition mutation identified in neuroblastoma was in *PHOX2B*.[74,75] *Phox2b* is a key regulator of autonomic neuron development, because its complete absence leads to embryonic lethality in mice as a result of the failure of sympathetic nervous system formation.[38,76] This gene is transiently expressed in murine primary sympathetic neuron progenitors from E10.5 to E13[76] and regulates their differentiation.[77-79] *Phox2b* also has growth inhibitory effects, because its overexpression promotes cell cycle exit and inhibits the proliferation of cultured sympathetic neurons.[80,81]

Heterozygous germline mutations of the *PHOX2B* gene occur in pedigrees and are associated with neuroblastoma, ganglioneuroblastoma, congenital central hypoventilation syndrome, and Hirschsprung disease.[74,75,82-85] The human *PHOX2B* gene maps to chromosome 4p13 and consists of three exons encoding a highly conserved 314–amino acid protein with two polyalanine repeats of 9 and 20 residues C-terminal to the homeodomain. Whereas the *PHOX2B* variants in congenital central hypoventilation syndrome largely involve expansions of the second polyalanine repeat within the C-terminus of the protein,[86-88] those associated with neuroblastic tumors are nearly always frameshift and truncation mutations.[74,75,85,86,89] More recently, whole-allele deletions resulting in the reduction of the protein have been reported.[90] Proposed mechanisms contributing to neuroblastoma predisposition include partial loss of function with the preserved ability to suppress cellular proliferation but not to promote differentiation,[83] complete loss of function due to functional haploinsufficiency,[91] and both dominant-negative and gain-of function effects.[81,92,93] Mutated *PHOX2B* also suppresses proliferation in vitro; heterozygous insertion of two frameshift variants, 931del5 and 693del8, into the mouse *Phox2b* locus resulted in impaired proliferation of sympathetic ganglion progenitors and biased differentiation toward the glial lineage.[93] Aberrant *Phox2b* expression in the zebrafish models has been shown to cause an arrest in the normal maturation of sympathetic neurons, leading to immature cells that are resistant to retinoic acid-induced differentiation.[94] Allelic deficiency of *PHOX2B* causes a decrease in the terminal differentiation markers *th* and *dbh* in sympathetic ganglion cells.[94] The neuroblastoma-associated frameshift mutations 676delG and K155X—but not the R100L missense mutation—functioned dominant negatively to impede differentiation.[94] Thus a reduced dosage of *PHOX2B* during development, through either a heterozygous deletion or dominant-negative mutation, imposes a block in the differentiation of sympathetic neuronal precursors, resulting in an immature cell population that is likely to be susceptible to secondary transforming events. The block in differentiation of immature sympathetic neurons caused by certain *PHOX2B* variants could be due to their inability to bind to interacting proteins critical to this process.[95] The neuronal calcium sensor protein HPCAL1 (VILIP-3) exhibits strong binding to wild-type *PHOX2B*, but only weakly or not at all to neuroblastoma-associated frameshift and truncation variants leading to impaired subcellular localization of HPCAL1 and impaired differentiation in vitro.

Anaplastic Lymphoma Kinase Mutations

Dominant mutations in the anaplastic lymphoma kinase (ALK) tyrosine kinase receptor have been identified in approximately 50% of familial neuroblastoma cases.[96,97] Several distinct germline mutations have been described to date—R1275Q, R1192P, T1151R, and G1128A—with R1275Q being the most frequent (Table 54-1). ALK germline mutations generally occur in the context of multifocal tumors, although in one study, affected patients

did not necessarily have younger age of onset. Further guidelines on screening need to be derived from a consensus analysis of inherited cases, but it would seem that in addition to a family history, the presence of multifocal tumors would call for genetic screening. In fact, in the United States, genetic testing for *ALK* and *PHOX2B* mutations is recommended for every newly diagnosed patient with a family history of neuroblastic tumors.

Germline Susceptibility Variants

Genome-wide association studies have identified SNPs within or adjacent to genes that predispose to sporadic neuroblastoma: *BARD1* (BRCA1-associated RING domain 1), *LINC00340* (long intergenic nonprotein coding RNA 340, *CASC15*), *LMO1* (LIM domain only 1), *DUSP12* (dual-specificity phosphatase 12), *DDX4/IL31RA* (DEAD box polypeptide 4/interleukin [IL]31 receptor A), *HSD17B12* (hydroxysteroid [17-beta] dehydrogenase 12), *LIN28B* (lin-28 homolog B), and *HACE1* (HECT domain and ankyrin repeat containing E3 ubiquitin protein ligase–1).[98-102] The *BARD1* SNP effect at chromosome 2q35 has been confirmed in African-American children,[5] and the *BARD1β* isoform[103] and *LIN28B*[104] are oncogenic in neuroblastoma. Patients with neuroblastoma who were homozygous for the risk alleles were more likely to have metastatic disease, amplification of *MYCN* (v-myc avian myelocytomatosis viral oncogene neuroblastoma-derived homolog), and disease relapse.[105] However, the absolute risk conferred by the susceptibility allele is extremely small,[105] and the risk that neuroblastoma may recur in families with these risk alleles is estimated to be very low.[106] A common copy number variation at 1q21.1 was also associated with neuroblastoma, the significance of which is uncertain.[99] The mechanisms through which these risk alleles and associated genes contribute to neuroblastoma initiation and/or maintenance require further investigation.

Genetic Aberrations in Sporadic Neuroblastoma

DNA Ploidy

Neuroblastomas are classified into those with diploid modal chromosomal content (with a deoxyribonucleic acid [DNA] index of 1) or hyperdiploid modal chromosomal content (DNA index greater than 1). Hyperdiploidy is associated with whole chromosome gains and overall favorable biology, whereas diploidy is associated with segmental chromosomal rearrangements and unbalanced translocations. Such segmental chromosomal aberrations seem to affect certain chromosomes—1p, 11q, and 17q—although the biologic significance is unclear at present.[107] Hyperdiploid tumors are often localized and have a favorable outlook, whereas diploid tumors not only tend to have a poor prognosis but also are associated with other high-risk genetic aberrations and *MYCN* amplification. Originally, infants (those younger than 1 year) with a hyperdiploid modal chromosome number were found to respond well to conventional therapy, whereas those with advanced stage disease with diploidy failed to respond to conventional therapy.[108,109] Subsequent studies have shown that tumor cell ploidy predicts responsiveness to therapy in children up to 18 months of age with advanced stage neuroblastoma without MYCN amplification.[110]

MYCN Amplification

MYCN, the first oncogene proven to be of clinical significance in neuroblastoma and gene amplification, occurs in approximately 20% to 30% of primary tumors and 90% of cell lines.[111,112] *MYCN* amplification is generally associated with advanced disease, poor outcome, and rapid tumor progression in neuroblastoma.[112,113] It occurs in 5% to 10% of early stage tumors and in half of the tumors of patients with advanced stage disease.[114,115] The detection of *MYCN* gene amplification in tumor cells at diagnosis is used by most cooperative groups to stratify patients to more intensive therapy. *MYCN* copy number appears to be consistent throughout the natural course of the disease, that is, at diagnosis and relapse and between primary and metastatic tumors in individual patients.[116] The Children's Oncology Group (COG) currently classifies *MYCN* amplification as more than 10 copies per diploid cell; it is unclear whether lower levels of gain (i.e., *MYCN* copy number between 3 and 10) confer an adverse outcome. A correlation usually exists between amplification and increased *MYCN* expression, and tumors with *MYCN* amplification generally express higher levels of MYCN than do nonamplified tumors; however, it has been reported that high expression is not linked to outcome.[117] *MYC* deregulation is common in high-risk tumors without *MYCN* amplification,[118] suggesting that MYC signaling could contribute to the high-risk phenotype.

Amplification manifests cytogenetically as double minutes or homogeneously staining regions; the latter occur mainly in tumors and the former in cell lines (Fig. 54-2).[119-121] However, there is no difference in clinical outcome whether *MYCN* amplification is manifested as double minutes or homogeneously staining regions in tumor samples obtained at diagnosis.[122] The genomic region amplified with *MYCN* is around 500 to 1000 kb, and several genes have been shown to be coamplified with *MYCN* in neuroblastoma. These genes include *DDX1* (DEAD box helicase 1),[123-125] *NAG* (*NBAS* [neuroblastoma amplified sequence]),[126,127] and *NCYM (MYCNOS—MYCN opposite strand)*,[125,128,129] and it is possible that coamplification of these genes may contribute to the tumor phenotype.

Role of MYCN during Development. *MYCN* is a highly conserved bHLH leucine zipper transcription factor located on chromosome 2p24.3 and a member of the *myc* family of oncogenes. The coding regions of both *MYC* and *MYCN* are highly homologous, with each having long 5′ and 3′ untranslated regions and gene products of similar sizes.[130,131] Both dimerize with Max and bind DNA at consensus E-box sequences (CANNTG; reviewed in reference 132).[132] Mice homozygous for disrupted MYCN die at around 10 days of gestation and have multiple organ defects, including tissues of the central and peripheral nervous systems, mesonephros, lung, gut, and heart.[133,134]

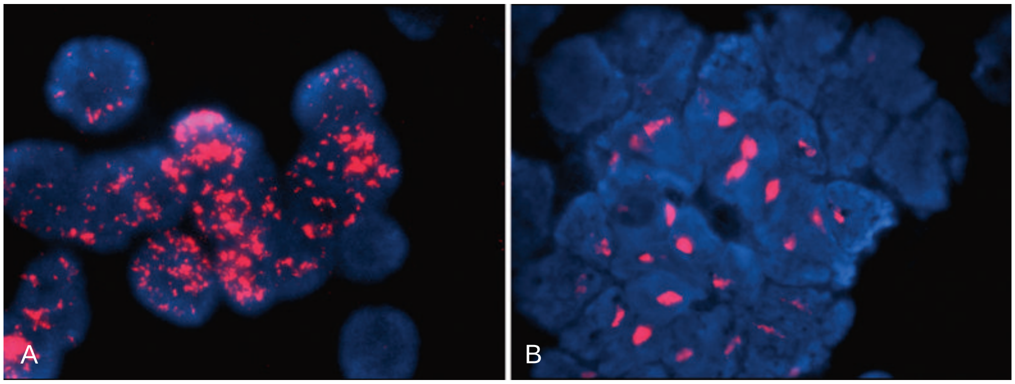

Figure 54-2 V-myc avian myelocytomatosis viral oncogene neuroblastoma-derived homolog *(MYCN)* amplification in neuroblastoma. A fluorescence in situ hybridization image of neuroblastoma tumors depicting *MYCN* amplification manifested as (**A**) double minutes and (**B**) homogeneously staining regions.

MYCN is highly expressed in fetal and neonatal development, specifically in the forebrain, hindbrain, and kidney, but not in adult tissues.[135] MYCN is expressed in the fetal brain up to the onset of differentiation and is also present at high levels in neuroblasts migrating from the neural crest through the adrenal cortex.[136] MYCN regulates overlapping stem-related gene expression programs in neuroblastoma and neural stem cells. MYCN induces a stemlike state by blocking differentiation pathways and activating self-renewal and pluripotency factors such as KLF2 and KLF4 (Kruppel-like factor 2 and 4) and LIN28B.[137,138]

Role of MYCN in Tumorigenesis. Suppression of MYCN expression in neuroblastoma cell lines results in a more differentiated phenotype.[139] Indeed downregulation of MYCN occurs in neuroblastoma cells induced to differentiate with chemical agents, and MYCN overexpression can block retinoic acid–induced differentiation.[140,141] Deletion of MYCN in neural progenitor cells showed decreased brain size and an increase in neuronal differentiation.[142] Enhanced expression of MYCN and the mutant H-*ras* gene cause tumorigenic conversion of primary rat embryo fibroblasts, and these transformed cells elicit tumors in athymic mice and isogenic rats.[143,144] Targeted expression of MYCN to the neuroectoderm of mice using a tyrosine hydroxylase promoter resulted in neuroblastoma tumors with chromosomal copy number abnormalities syntenic to those found in human tumors.[145,146] The prolonged latency together with the additional chromosomal anomalies in these tumors suggests that additional genetic mutations are required for neuroblastoma formation.

MYCN is involved in all aspects of tumor cell metastasis: adhesion, motility, and invasion (reviewed in reference 132). It downregulates integrins α1 and β1 to allow invasion.[147,148] MYCN-amplified tumors have increased angiogenesis: overexpression of MYCN is associated with proangiogenic factors such as angiogenin and vascular endothelial growth factor (VEGF) through the PI3K/mTOR (mammalian target of rapamycin) pathway.[149]

Role of MYCN in Altered Tumor Metabolism. Similar to other cancers, neuroblastomas require abnormally high amounts of glucose and other macromolecules to enable their continued unchecked proliferation. These needs are met through alterations in key metabolic pathways that can potentially be harnessed for the development of new anticancer therapies.[150]

Normal cells generate adenosine triphosphate (ATP) from glucose through oxidative phosphorylation when oxygen is abundant. During oxygen deprivation, which occurs commonly in solid tumors, including neuroblastoma, ATP generation occurs through glycolysis (the Warburg effect). Genes involved in glycolysis are selectively activated by hypoxia-inducible factor–1α (HIF1a), which is upregulated in hypoxic states. HIF1a is preferentially expressed in MYCN-amplified neuroblastoma cells; moreover, high levels of MYCN have been shown to override HIF1a inhibitory effects on cell cycle progression, thus enabling continued proliferation under hypoxic conditions.[151] Therefore both deregulated MYCN and HIF1a cooperate to contribute to the Warburg effect in neuroblastoma cells. Moreover, expression of glycolytic genes phosphoglycerate kinase 1 *(PGK1)*, hexokinase 2 *(HK2)*, and lactate dehydrogenase A *(LDHA)* were higher in MYCN-amplified neuroblastoma than in those without MYCN amplification, with depletion of LDHA inhibiting tumorigenesis in vivo, suggesting that these metabolic pathways could be targeted therapeutically.

MYCN-amplified cells have also been shown to depend on exogenous glutamine for their survival. MYCN-amplified neuroblastoma cells overexpress high-affinity glutamine transporters and other glutaminolytic enzymes that correlate with poor prognosis. Glutamine depletion in MYCN-amplified neuroblastoma cells led to apoptosis through p53-independent PUMA (p53-upregulated modulator of apoptosis) and NOXA induction,[152] an effect that is mediated by activation of the activating transcription factor–4 (ATF4). ATF4 has both context-dependent prosurvival and proapoptotic effects. In MYCN-amplified cells, it appears to have a prodeath role, because ATF4 agonists and glutaminolysis inhibitors potently induced apoptosis in vitro and inhibited tumor growth in vivo, suggesting that ATF4 agonists could be potential therapeutics for MYCN-amplified neuroblastomas.[152]

MYCN in Immune Surveillance. MYCN is also important in immune surveillance in that it represses several chemoattractant proteins that are required for recruitment of natural killer T cells (NKTs).[153] NKTs are important for producing proinflammatory cytokines to recruit immune cells, stimulate the maturation of dendritic cells, and generate antigen-specific T cells to target the tumor. Patients with MYCN-amplified neuroblastoma with bone marrow metastases had fewer bone marrow NKTs. One such protein repressed by MYCN is monocyte chemoattractant protein–1/chemokine (C-C motif) ligand 2 (MCP-1/CCL2).[153] Deletion of MYCN in MYCN-amplified cells rescues MCP-1 production and NKT recruitment. Therefore avenues to improve NKT function are being explored as therapeutic modalities in neuroblastoma.

ALK Amplification and Mutation

The identification of somatic mutations in the ALK receptor in neuroblastoma represents the first therapeutically targetable genetic aberration in this disease.[96,97,154,155] ALK, a cell surface tyrosine kinase receptor of the insulin receptor superfamily, is located in humans at chromosome 2p23 and contains an extracellular ligand-binding domain, a transmembrane domain, and an intracellular tyrosine kinase domain (reviewed in reference 156).[156,157] Ligand binding leads to receptor dimerization and activation via trans-autophosphorylation of tyrosine residues.[158] The 177-kDa polypeptide encoded by the human *ALK* gene undergoes posttranslational modification, such as N-glycosylation, to generate a mature protein doublet of 220 and 190 kDa.[158] ALK is preferentially expressed in the central and peripheral nervous systems during development (i.e., thalamus, hypothalamus, midbrain, cranial ganglia and olfactory bulb, and dorsal root ganglia).[159] ALK levels decrease postnatally, so that in adults ALK expression is restricted to rare scattered neural cells, endothelial cells, and pericytes in the brain.[159-161] The physiologic function of ALK is not clear, although its predominant expression in the nervous system during development suggests that it likely plays an important role in the development of the nervous system. Homozygous ALK-null mice are viable and develop without obvious anatomic abnormalities and a normal life span,[162] other than increased basal dopaminergic signaling within the prefrontal cortex and an age-dependent increase in basal hippocampal progenitor proliferation,[162] as well as mild behavioral phenotypes.[163,164] In *Drosophila melanogaster*, the receptor is important for the development of visceral gut musculature because absence of dALK leads to the loss of mesodermal founder cells responsible for gut development.[165] The zebrafish alk ortholog is expressed at high levels in the developing nervous system.[166] Ectopic expression of alk during early neurogenesis results in increased cell proliferation and aberrant neurogenesis in the central nervous system (CNS), leading to mispositioning of differentiated neurons and activation of the MEK/ERK pathway. Morpholino-mediated and pharmacologic depletion of alk, however, did not affect neuron progenitor formation, but it did cause compromised neuronal differentiation and survival in the CNS.[166]

Signaling by the Wild-Type ALK Receptor. Pleotropin (PTN) and midkine (MK) have been reported as candidate ligands of mammalian ALK.[167,168] Whether PTN and MK are true ligands of ALK remains controversial because some groups have failed to reproduce the binding and activation of ALK by PTN.[169-171] Signaling by these two molecules may trigger dimerization and phosphorylation of ALK, leading to activation of downstream signaling pathways. In *D. melanogaster* and *Caenorhabditis elegans*, the ALK ligands are Jelly belly (Jeb)[172] and hesitation behavior 1 (HEN1),[173,174] respectively, with Jeb being structurally different from either PTN or MK.[175] Ligand activation of ALK has been implicated in the inhibition of apoptosis and induction of neuronal cell differentiation through the mitogen-activated protein kinase (MAPK) pathway.[176-178] Signaling through the phospholipase Cγ (PLCγ) pathway by activated ALK, leading to transformation of NIH 3T3 cells, has also been reported.[179]

ALK Mutations in Neuroblastoma. In human tumors the most common mechanism of constitutive ALK activation involves chromosomal translocations that result in the generation of oncogenic *ALK* fusion genes, such as nucleophosmin *(NPM1)-ALK* in anaplastic large cell lymphoma[180] and echinoderm microtubule-associated protein like 4 *(EML4)-ALK* in non–small cell lung cancers (NSCLCs),[181] among others.[182] ALK translocations have not yet been reported in neuroblastomas, apparently because the ALK receptor is normally expressed by sympathetic neuroblasts, and a heterologous promoter does not need to be provided through translocation. Rather, ALK aberrations take the form of point mutations, amplification, and copy number gain. Activating mutations in ALK occur in 7% to 8% of sporadic neuroblastomas.[154,155,97,183-186] ALK is also amplified in neuroblastoma, although always in combination with MYCN amplification, and amplified ALK appears to mediate overexpression alone in that the affected ALK allele does not harbor activating point mutations.[155]

Altogether 12 different residues are known to be affected by ALK mutations (Table 54-1).[156] Mutations range from silent to activating, with the two major mutational hot spots being R1275 and F1174; the R1275Q mutation is found in both familial and sporadic neuroblastoma, whereas the F1174L mutation is restricted to sporadic tumors, presumably because it is embryonic lethal. Activating ALK mutations are associated with constitutive phosphorylation of ALK and that of downstream targets such as ERK, STAT3, and AKT.[156] These ALK variants are for the most part retained intracellularly in the endoplasmic reticulum and Golgi and exhibit impaired maturation with defective N-linked glycosylation.[187] Moreover, the constitutive activity of these variants does not require receptor dimerization.[187] Their oncogenic potential has been demonstrated by cytokine-independent growth,[155,184] transformation of NIH-3T3 fibroblasts in soft agar colony formation assays,[154] and tumor formation in nude mice.[154] Knockdown of ALK in ALK-mutant neuroblastoma cell lines led to significant inhibition of cell proliferation and induction of cell death, further emphasizing the strong oncogenic "addiction" of these cells to mutationally activated ALK.[155]

Elucidation of the crystal structure of ALK in its inactive conformation and mapping of neuroblastoma-associated mutations has shown that many of the ALK residues that become mutated in neuroblastoma play structural roles in autoinhibition of ALK.[188,189] Mutations allow unrestricted mobility of the alphaC helix, phosphate-binding loop, and N-terminal lobe, leading to kinase activation. Both the F1174L and R1275Q mutants show accelerated catalytic efficiency compared with wild-type ALK, with R1275Q exhibiting approximately fourfold increased catalytic efficiency and F1174L exhibiting approximately eightfold increased catalytic efficiency compared with the wild-type enzyme. This increased catalytic efficiency is at least partly due to the enhanced ATP binding affinity of these mutations for both ATP and peptide substrate.[189,190]

The ALK mutants show varying degrees of transformation capabilities. *ALK*^{F1174L} is considered the most aggressive of all *ALK* mutations in neuroblastoma, possessing higher transforming potential and kinase activity.[184] Importantly, *ALK*^{F1174L} also arises secondarily as a mechanism of resistance after an initial response to crizotinib in patients with *ALK*-rearranged cancers.[191] Moreover, the F1174L mutation cosegregates with MYCN amplification in patients with neuroblastoma, and this combination is associated with a particularly poor prognosis.[184] ALK^{F1174L} potentiates the oncogenic activity of MYCN in vitro[192,193] and in vivo,[194-196] although by itself, ALK^{F1174L} appears to be insufficient to cause the malignant transformation of neural crest–derived stem cells.[194,195] When crossed with MYCN transgenic mice, mice overexpressing ALK^{F1174L} in neural crest–derived cells gave rise to doubly transgenic progeny that developed aggressive neuroblastoma with 100% penetrance and a very short latency period.[194] ALK^{F1174L}/MYCN tumors exhibited increased MYCN dosage due to ALK^{F1174L}-induced activation of the PI3K/AKT/mTOR and MAPK pathways, coupled with suppression of MYCN pro-apoptotic effects.[194] Similarly, coexpression of ALK^{F1174L} and MYCN in zebrafish markedly increased the frequency of tumor formation and accelerated the time of onset.[195] MYCN overexpression induces adrenal sympathetic neuroblast hyperplasia, blocks chromaffin cell differentiation, and ultimately triggers a developmentally timed apoptotic response in the hyperplastic sympathoadrenal cells. Coexpression of activated ALK with MYCN provides prosurvival signals that block this apoptotic response and allow continued expansion and oncogenic transformation of hyperplastic neuroblasts, thus promoting progression to neuroblastoma.[195]

ALK mutations show no predilection for particular clinical stages of tumor progression.[185] With the exception of F1174L mutations that occur preferentially in MYCN-amplified tumors, somatic ALK mutations do not appear to be associated with survival,[184] although a more recent study reported that mutation-positive cases had a decreased overall survival (OS) probability.[197] However, ALK overexpression in the absence of mutation or amplification does appear to be associated with OS.[186,198] ALK RNA and protein overexpression is detectable in approximately 90% of primary tumors[199] and in some reports is associated with activation of downstream signaling.[200,201] The significance of this phenomenon, as well as the mechanism underlying activation of ALK, is presently unclear. Passoni et al.[198] (2009) argue that it is the level of expression that dictates oncogenicity, based on the fact that constitutive phosphorylation of ALK was observed in cells with high expression, whereas those with low expression lacked activation. This observation, plus the fact that genetic knockdown of wild-type ALK caused a decrease in cell proliferation,[97] suggest that overexpression of wild-type ALK may have some degree of proproliferative activity. Other studies have shown that neuroblastoma with elevated expression of wild-type ALK had clinical and molecular phenotypes similar to those of tumors with mutated *ALK* gene expression.[186] These data suggest that mechanisms other than mutation and amplification can lead to ALK activation.

ALK Amplification. ALK is amplified in around 2% to 3% of primary neuroblastoma cases.[184] Amplification tends to coexist with MYCN amplification; in fact, ALK amplification has been detected in up to 15% of primary neuroblastomas with MYCN amplification.[155,169,202] ALK amplification does not appear to have any independent prognostic value in neuroblastoma. ALK copy number gain appears to be more common than mutation or amplification, occurring in 15% to 20% of cases,[184,185] and usually involves whole chromosome 2 gain. Such chromosome 2p gains are associated with significantly increased ALK expression, correlating with poor survival.[97,184,198]

ALK Signaling in Neuroblastoma. Constitutively activated ALK as a result of ALK amplification binds to the activated Src homology 2 domain–containing adaptor protein ShcC and thereby activates downstream signaling.[169] Inhibition of this binding impairs survival, differentiation, and motility of neuroblastoma cells through blockage of the MAPK and PI3K/AKT pathways and impairs the induction of apoptosis.[201] Gain-of-function ALK mutations also commonly signal through the MAPK, PI3K/AKT/mTOR, and STAT pathways to regulate cell growth, transformation, and antiapoptotic signaling (reviewed in references 156 and 157).

ATRX Mutations

The alpha thalassemia/mental retardation syndrome X-linked *(ATRX)* gene is mutated primarily in 44% of neuroblastoma tumors in adolescents and young adults, which largely have an indolent tumor phenotype compared with that in children and infants.[203,204] These loss-of-function mutations are associated with absence of the ATRX protein in the nucleus and telomere lengthening, the mechanism of which is unclear. ATRX is involved in the regulation of ATP-dependent chromatin remodeling, nucleosome assembly, and telomere maintenance. ATRX also plays a role in epigenetic regulation of gene expression by controlling the deposition of histone H3.3 at transcriptionally silent regions of the genome, which may potentially lead to increased expression of oncogenes in tumors with ATRX mutations. ATRX mutations correlate with older age at diagnosis (age >5 years) and chronic or indolent disease. The *ATRX* gene is present on the X chromosome, and both males and females were affected. These mutations are not thought to be associated with MYCN amplification, although further studies are required to validate this supposition.[204]

Chromosomal Abnormalities in Neuroblastoma

Chromothripsis

Chromothripsis is a phenomenon that has been recently identified in 18% of high-stage neuroblastomas.[203] Chromothripsis[205] is a local shredding of chromosomes with subsequent random reassembly of the fragments. These structural alterations recurrently affected *ODZ3* (*TENM1* [teneurin transmembrane protein 1]), *PTPRD* (protein tyrosine phosphatase, receptor type, D), and *CSMD1* (CUB and Sushi multiple domains 1) genes involved in neuronal growth cone stabilization.[203] ODZ3 and PTPRD encode transmembrane receptors expressed in the developing nervous system localizing to axon and axonal growth cones.[206] Chromothripsis-related structural aberrations were associated with amplification of *MYCN* or cyclin-dependent kinase–4 *(CDK4)* and loss of heterozygosity (LOH) of chromosome 1p.[203]

1p Loss of Heterozygosity

LOH of the short arm of chromosome 1p is a common occurrence in neuroblastoma.[207] The common region of LOH is within 1p36.2-1p36.3.[208-210] However, this region may be much larger, extending from 1p35 to the terminal end.[211-213] This abnormality has been reported not only in neuroblastoma but also in melanoma, pheochromocytoma, and medullary thyroid carcinoma, all of which are neural crest–derived tumors.[214-216] LOH of 1p occurs in 30% to 40% of neuroblastomas[217] and is positively correlated with older age, advanced stage, MYCN amplification, and a poor outcome.[218] When MYCN amplification and 1p LOH are present together, they define a genetically distinct and very aggressive subset of neuroblastoma.[219] Because cases with MYCN amplification represent a subset of patients with 1p deletion (because MYCN amplification is rarely found in the absence of 1p deletion), it is believed that 1p deletion may precede the development of MYCN amplification. Although 1p loss is also present in almost all samples with MYCN amplification, it is also found in high-risk cases without MYCN amplification.[217]

Therefore it follows that loss or inactivation of a gene or genes on 1p would be critical for the development or progression of neuroblastoma. This scenario has been suggested by reports of constitutional 1p36 alterations in patients with neuroblastoma.[220] Transfection of chromosome 1p into a neuroblastoma cell line restores a differentiated phenotype and abrogates tumorigenicity.[221] In addition, cell fusion experiments between MYCN amplified and single copy cells have resulted in abrogation of MYCN expression, suggesting than MYCN could be regulated by a gene located on 1p.[213] Several candidate tumor suppressor genes have been identified, including *CHD5* (chromodomain helicase DNA binding protein 5),[222-224] *KIF1B* (kinesin family member 1B),[225,226] *TP73* (tumor protein p73),[227] *MIR34A* (microRNA 34A),[228] *CAMTA1* (calmodulin binding transcription activator),[229] and *CASZ1* (castor zinc finger 1).[230]

CHD5. CHD5, a member of the CHD family of proteins involved in chromatin remodeling, is preferentially expressed in the nervous system and maps to a small region of deletion on 1p36.3 in neuroblastomas.[224] Expression of CHD5 has been found to be low or absent in cell lines and tumors with 1p deletion. Low expression of CHD5 is also highly correlated with MYCN amplification, advanced stage, and unfavorable histology.[224,231] When CHD5 was expressed in neuroblastoma cell lines with low or absent expression, clonogenicity and tumor growth were abrogated.[223] Mouse models with loss of a region corresponding to human 1p36 implicated CHD5 as a tumor suppressor that controls proliferation, apoptosis, and senescence via the $p19^{Arf}$/p53 pathway.[222] *CHD5* mutations, however, are rare in neuroblastoma,[224] although it is now becoming clear that complete inactivation of the gene does not appear to be necessary for malignant transformation. Rather, gene dosage may be another mechanism that regulates tumor suppressor activity as shown for some *PHOX2B* mutations.[94] In a study by Bagchi et al.,[222] (2007) increased dosage of CHD5 (as in wild-type or three copies) led to tumor-suppressive properties, whereas decreased dosage (as in heterozygous 1p deletion) enhanced immortalization, spontaneous foci formation, and sensitivity to oncogenic transformation. In addition, it has been suggested that almost complete inactivation of the second allele may occur by an epigenetic phenomenon because the CHD5 promoter was found to be highly methylated in two cell lines that lacked CHD5 expression.[223]

KIF1B. The kinesin family member, KIF1B, is located on 1p36.2 and is thought to function as a tumor suppressor gene in neuroblastoma and pheochromocytoma.[226] Germline loss-of-function mutations have been detected in patients with neuroblastoma, leading to abrogation of the apoptosis that is a requisite to normal neuronal developmental culling when nerve growth factor (NGF) becomes limiting. Neuroblastoma cells have been shown to undergo apoptosis when NGF is withdrawn, which is mediated through the EglN3 prolyl hydroxylase. KIF1B acts downstream of EglN3.[232,233] Similar to the case with CHD5, KIF1B haploinsufficiency may be sufficient for loss of its tumor suppressor activity, especially if combined with loss or abnormalities of other genes on 1p36 such as CHD5.[222] In support of this theory, when KIF1B levels were decreased to 50% using short hairpin (sh)RNA knockdown, inhibition of apoptosis was observed.[226]

CASZ1. Deletion of CASZ1, a neuronal differentiation gene, has been implicated in neuroblastoma tumorigenesis.[229,234-236] CASZ1 is the human homologue of the *Drosophila* zinc finger transcription factor, castor.[237] Low expression of CASZ1 via LOH or epigenetic suppression is associated with poor prognosis in patients with neuroblastoma.[234,238] Moreover, the restoration of CASZ1 in neuroblastoma cells suppresses cell proliferation by activation of pRB in G1 and inhibition of the G2/M regulators cyclin B1 and Chk1 and induces cell differentiation.[234,235] Decreased CASZ1 expression in neuroblastoma is thought to be due to upregulation of one of the three core subunits of the polycomb repressor complex 2, EZH2 (enhancer of zeste 2).[238] This methyltransferase regulates trimethylation of histone H3 on lysine 27 (H3k27me3 [histone H3 trimethyl lysine 27]), which is associated with gene silencing. Analysis of expression data sets revealed that patients with neuroblastoma who have a poor prognosis have increased levels of EZH2 expression.[238] Silencing of EZH2 leads to decreased H3K27me3 and increased expression of CASZ1. Thus a model has been suggested in which one allele of CASZ1 could be lost by 1p LOH, with the remaining allele epigenetically silenced by EZH2-mediated H3k27me3. Moreover, EZH2 also was found to silence a number of tumor suppressors that control differentiation in neuroblastoma, such as clusterin *(CLU)*, runt-related transcription factor–3 *(RUNX3)*, and nerve growth factor receptor *(NGFR)*. Genetic and pharmacologic inhibition of EZH2 inhibited neuroblastoma cell growth and induced differentiation.[238]

MIR34A. The microRNA (miRNA)-34a *(MIR34A)* on 1p36.23 is expressed at lower levels in primary tumors and cell lines with 1p deletion and is also thought to function as a tumor suppressor gene.[228,239,240] Reintroduction of this miRNA into neuroblastoma cell lines with 1p deletion causes a dramatic reduction in cell proliferation through the induction of a caspase-dependent apoptotic pathway and by reducing levels of E2F3, a transcriptional inducer of cell-cycle progression. *MIR34A* also increases during retinoic acid–induced differentiation of neuroblastoma cells.[239,241] Indeed, targeted delivery of miRNA-34a using nanoparticles conjugated to an anti-GD2 antibody that is expressed on the surface of virtually all neuroblastoma cells was shown to result in decreased tumor growth in orthotopic xenograft models, highlighting its therapeutic potential.[242] In addition, *MIR34A* has also been found to directly target and downregulate MYCN and B-cell lymphoma–2 (BCL2).[240] *MIR34A* causes significant suppression of cell growth through increased apoptosis and decreased DNA synthesis in neuroblastoma cell lines with MYCN amplification.[228]

ARID1 Mutations. Deletions and sequence alterations in the chromatin-remodeling genes *ARID1A* and *ARID1B* (AT-rich interactive domain 1A and 1B) have been reported in 11% of tumors.[243] These mutations were associated with early treatment failure and decreased survival. ARID1 family genes are integral components of the switch/sucrose nonfermentable (SWI/SNF) neural progenitor-specific chromatin-remodeling BRG1-associated factor (BAF) complex that is essential for the self-renewal of multipotent neural stem cells.[244] ARID1A was affected by insertional and point mutations predicted to result in premature termination of the protein and deletion of the other allele at 1p36, largely leading to biallelic inactivation.[243] Hemizygous deletions encompassing the whole coding sequence, intragenic hemizygous deletions, and splice-site and missense mutations targeting ARID1B were also reported in this study. High expression of members in the neural progenitor BAF complex correlated with a high-risk neuroblastoma phenotype, whereas high expression of components of the neuron-specific BAF complex or downstream neuritogenesis target genes correlated with low-risk neuroblastoma.[243] Thus it is possible that disrupted BAF complex signaling preserves an undifferentiated progenitor state, although this preservation has not as yet been demonstrated.

LIN28B Overexpression

Overexpression of the *LIN28B* gene that encodes a protein that binds small RNAs has been reported in neuroblastoma.[104] Lin28b is highly expressed in stem cells and developing tissues and regulates germ cell development, skeletal myogenesis and neurogenesis, and glucose metabolism. It is a master regulator of pluripotency in embryonic stem (ES) cells, and in combination with *NANOG* (Nanog homeobox), *OCT4* (organic cation transporter–4), and *SOX2* (sex-determining region Y box–2), it can reprogram differentiated cells to pluripotent stem cells.[245-247] High LIN28B expression was found to be an independent risk factor for adverse outcome in persons with neuroblastoma. In neuroblastoma cells, *LIN28B,* through repression of the let-7 miRNA family, caused elevated MYCN expression and inhibition of normal neuroblast and neuroblastoma differentiation, whereas overexpression of LIN28B in nonmalignant neuroblasts drives proliferation. Targeted expression of LIN28B in the sympathetic adrenergic lineage induced development of neuroblastomas marked by low let-7 miRNA levels and high MYCN protein expression. Mechanisms underlying the overexpression of LIN28B in neuroblastoma are currently unclear.[104] *LIN28B* has also been identified in a genome-wide association study of patients with neuroblastoma as influencing susceptibility to neuroblastoma, and high expression was associated with worse OS.[248]

Chromosome 17q Gain

Gain of chromosome 17q is the most common cytogenetic abnormality in neuroblastoma; it occurs in more than 60% of neuroblastomas and is associated with an unfavorable prognosis[249] and metastatic disease.[250] Gain usually takes the form of one to three extra copies. The break points vary, but in general, gain of a region from 17q22-qter is observed. Partial gain often results from unbalanced translocation of 17q21-25 to another chromosome. Unbalanced 1;17 translocations occur in primary neuroblastoma and result in loss of distal 1p with gain of 17q material.[251] Unbalanced 17q gain is associated with MYCN amplification and most likely harbors an oncogene that contributes to neuroblastoma tumorigenesis. However, 17q translocation break points are not uniform and can involve other partner chromosomes, especially 11q.[252] The break point positions on 11q were found to be variable, whereas all break points on 17q appeared to cluster proximal to position 43.1 Mb on the DNA sequence map.[253]

Isogenic cell lines derived from MYCN-driven murine tumors in transgenic mice showed gains of regions syntenic with human 17q.[254] One of the candidate genes on 17q is survivin, the expression of which is significantly associated with a poor prognosis.[255] Other candidate genes in the 17q region are nm23-H1 and nm23-H2, which are both targets of MYCN. Nm23-H1 binds to Cdc42, which is encoded on 1p36 and prevents neuroblastoma cell differentiation. Overexpression of Nm23 due to gain of 17q and induction by MYCN combined with decreased expression of Cdc42 due to loss of 1p36 can block neuroblastoma tumor differentiation.[256]

Chromosome 11q LOH

Allelic loss of 11q occurs in 35% to 45% of primary tumors.[257,258] Chromosome transfer experiments involving transfer of an intact chromosome 11 into a neuroblastoma cell line induces differentiation.[221] The common region of deletion has been mapped to 11q23, indicating that this could be a location for a neuroblastoma suppressor gene.[259] Chromosome 11q loss is associated with multiple chromosomal breaks, possibly reflecting an underlying DNA repair defect.[260] Chromosome 11q LOH occurs mainly in tumors *without* MYCN amplification and identifies a high-risk subset of patients with advanced stage, older age, and disease with unfavorable histologic features. Unbalanced deletion of 11q occurs in 15% to 20% of cases and is associated with a poor event-free survival (EFS) in patients with otherwise low-risk and intermediate-risk disease (Fig. 54-3).[261]

Chromosome 14q LOH

Deletion of 14q has also been reported in 25% of neuroblastomas,[262-264] with a common region of deletion within 14q23-qter.[265] LOH for 14q is inversely related to 1p36 LOH, MYCN amplification, and 11q LOH.

Other areas of chromosomal gain noted especially in tumors with an aggressive clinical phenotype, but not MYCN amplification, include gain of 1q and 12q.[266] Chromosomal regions that have been deleted are 3p,[267] 4p,[217] 9p,[268] and 18q,[269] but these regions are all less common.

Neurotrophin Receptors in Neuroblastoma

Tropomyosin receptor kinase (TRK) receptors, when activated by their respective neurotrophins, mediate the survival and differentiation of neurons during development (reviewed in reference 270).[270] NGF-induced dimerization of TRKA (NTRK1) or brain-derived neutrotrophic factor (BDNF)–induced dimerization of TRKB receptors leads to activation of the tyrosine kinase domain, which facilitates binding of SHC and phosphotyrosine binding (PTB) domain protein adaptors and PLCγ protein binding, respectively, leading to activation of the major growth factor–regulated signaling pathways—the Ras/MAPK pathway and PI3K/3-phosphoinositide–dependent protein kinase–1 (PDK1)/AKT pathway—and to increases in Ca++ release and activation of the PLCγ pathway. The main ligand for TRKA, NGF, promotes survival and induces differentiation in developing sympathetic neuroblasts. Neuroblastoma tumor cells with high levels of TRKA expression differentiate in the presence of NGF in vitro but will undergo apoptosis in its absence.[271] Depending on the tumor microenvironment, therefore, TRKA signaling could induce differentiation or regression of favorable neuroblastomas. During normal development, depletion of NGF occurs in sympathetic neurons, causing TRKA signaling to activate predetermined apoptotic pathways. It has been postulated that spontaneous regression of neuroblastomas is but a delay in this normal developmental pattern.[92] A neurodevelopmentally regulated splice variant of TRKA, TrkAIII, has been identified that antagonizes the antioncogenic NGF/TRKA signaling and promotes neuroblastoma tumor growth.[272] High levels of TRKA expression are associated with a good prognosis in neuroblastoma and are strongly correlated with favorable tumor stage, younger age, and nonamplified *MYCN*. Patients with hyperdiploid tumors with favorable outcome identified by mass screening were also shown to have very high TRKA expression.[271]

The TRKB *(NTRK2)* transcript is expressed primarily in highly aggressive *MYCN*-amplified tumors.[273] The ligand for TRKB is BDNF, and activation of TRKB by BDNF leads to enhanced proliferation, migration, angiogenesis and resistance to chemotherapy in neuroblastoma.[274] Neuroblastoma cells that survive repeated exposures to cytotoxic agents express increasing levels of BDNF, suggesting that this pathway contributes to a multidrug-resistant phenotype.[275] Moreover, hypoxia induces increased TrkB expression and may contribute to a phenomenon in the tumor microenvironment where autocrine activation of the BDNF/TrkB signaling enables survival of residual tumor cells after repeated rounds of chemotherapy.[276] The full-length TRKB, which is expressed in about one third of tumors tested, is expressed primarily in those with *MYCN* amplification, whereas the truncated form resulting from alternative splicing, which lacks the tyrosine kinase domain, is expressed in ganglioneuromas and ganglioneuroblastoma.[273] The truncated TRKB is thought to sequester BDNF and thus prevent TRKB signaling.[277-279] Studies have shown that survival of neuroblastoma cells exposed to cytotoxic drugs is mediated partly by activation of the Trk receptor via PI3K,[280] activation of Akt,[281] and inactivation of glycogen synthase kinase–3 beta (GSK3B).[282] Thus the response of neuroblastoma cells to chemotherapeutic agents depends on the levels of BDNF; tumor cells expressing low levels of TrkB exhibit minimal effects on exposure to cytotoxic agents in the setting of a BDNF-rich environment. BDNF/TrkB-induced increases in HIF1a may lead to increased VEGF and angiogenesis in neuroblastoma.[283] Thus hypoxia-associated increases in neuroblastoma cell invasiveness can be blocked by inhibition of TrkB.[284] Activation of the BDNF/TrkB signaling pathway stimulates

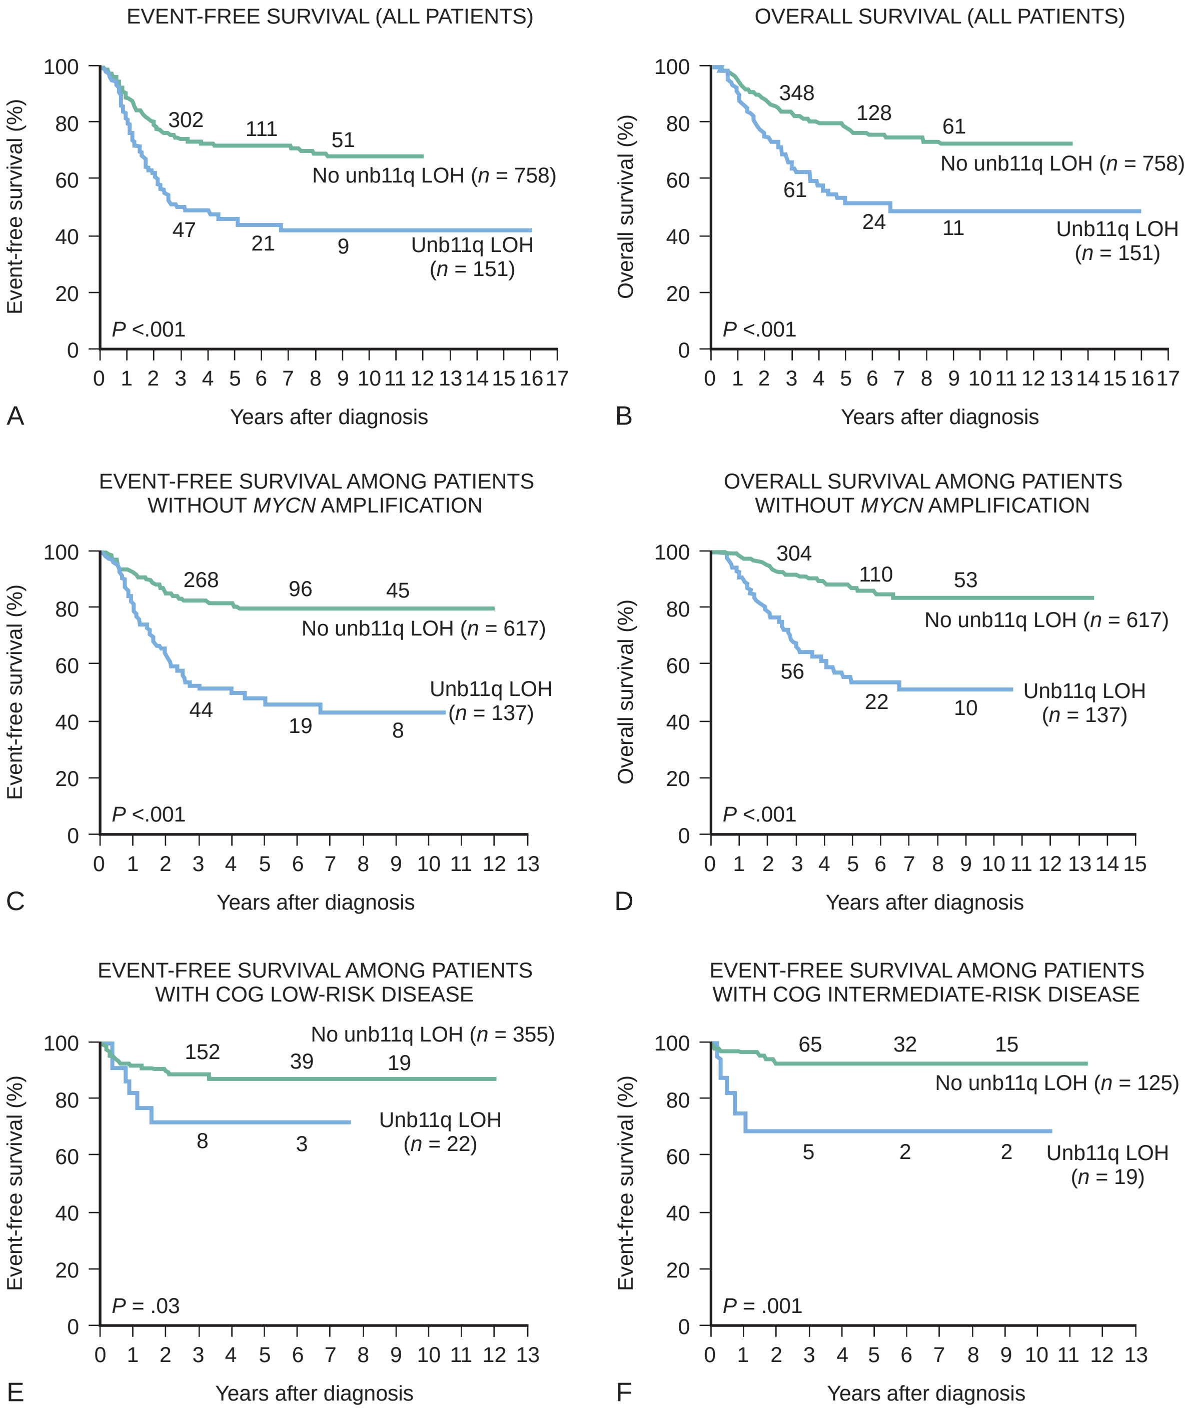

Figure 54-3 Survival according to unbalanced 11q loss of heterozygosity *(unb11q LOH)*. The rates of event-free and overall survival are shown for all patients (**A** and **B**), for patients whose tumors did not have v-myc avian myelocytomatosis viral oncogene neuroblastoma-derived homolog *(MYCN)* amplification (**C** and **D**), and event-free survival for those with low-risk disease (**E**) and intermediate-risk disease (**F**) as defined by the Children's Oncology Group *(COG)*. The numbers of patients at risk for an event are shown along the curves. *(From Attiyeh EF, London WB, Mosse YP, et al: Chromosome 1p and 11q deletions and outcome in neuroblastoma.* N Engl J Med *353:2243–2253, 2005.)*

tumor cell survival and angiogenesis and contributes to chemotherapy resistance and anoikis.[270]

TRKC, like TRKA, is involved in the biology of favorable neuroblastomas, and expression corresponds to lower stages.[285] Although its expression is found in 25% of primary neuroblastomas, it does not have independent prognostic significance, because all tumors with TRKC expression also have TRKA expression.

Apoptosis

In contrast to most human tumor types, the *p53* gene is very rarely mutated in neuroblastoma at diagnosis[286-289] but is found in chemotherapy resistance.[287,286] Other mechanisms of *p53* loss of function, such as cytoplasmic sequestration, mouse double minute 2 (MDM2 protooncogene) amplification, or TWIST-mediated suppression have been proposed, but their contribution appears to be limited.[290-292] Although basal p53 expression in neuroblastoma cells is largely confined to the cytosol, p53 protein levels were found to increase mainly in the nucleus after radiation-induced DNA damage.[293]

Epigenetic modification of the pro-apoptotic gene caspase-8 has been observed in neuroblastomas.[294,295] Up to 70% of human neuroblastoma cell lines and 25% of primary tumors tested lack caspase-8 expression and fail to undergo apoptosis.[294,296,297] Loss of expression of both caspase 8 (apoptosis-related cysteine peptidase, *CASP8*) alleles is correlated with methylation of the caspase-8 gene,[294] and treatment with the demethylating agent decitabine restored caspase-8 expression[296,298] and increased susceptibility to doxorubicin-induced apoptosis.[294] In addition, methylation has been shown to be the mode of silencing of other genes involved in apoptosis: the four tumor necrosis factor–related apoptosis-inducing ligand (TRAIL) apoptosis receptors and the caspase-8 inhibitor FLICE-like inhibitory protein (FLIP).[296,299]

Overexpression of BCL2, an inhibitor of apoptosis, has been found to be associated with unfavorable histology and MYCN amplification.[300] Neuroblastoma cells and tumors are primed for death with sequestration of BIM, a direct activator of apoptosis, either by the prosurvival BCL-2 or myeloid cell leukemia–1 (MCL-1) proteins.[301] This pattern of survival dependency has been shown to predict the pattern of response to Bcl-2 antagonists. The Bcl-2/Bcl-xl/Bcl-w inhibitor ABT-737 was active against Bim:Bcl-2 primed tumor xenografts but not against cells where Bim was sequestered by Mcl-1. In isogenic cell lines at diagnosis and relapse, therapy resistance was shown not to be mediated by upregulation of Bcl-2 family members or loss of Bim priming but by repression of Bak and/or Bax-mediated apoptosis.[301]

Therapy Resistance

The multidrug resistance gene encoding P-glycoprotein is thought to function by causing enhanced drug efflux from the cell, and its overexpression has been found to predict outcome of therapy for neuroblastoma.[302,303] The multidrug resistance-associated protein (MRP), like P-glycoprotein, mediates resistance to a number of drugs.[304,305] MRP is expressed by neuroblastoma tumors of all stages. Tumors with *MYCN* amplification have been shown to have significantly higher expression levels of MRP than do those with normal *MYCN* copy numbers. Reduced MRP expression levels correlate with differentiation of neuroblastoma cells in vitro.[306] In addition, an association has been found between high levels of MRP expression and poor outcome, which is independent of *MYCN* amplification.[307] It is possible that both multidrug resistance protein–1 (MDR1) and MRP function together with several other factors that confer resistance to drug therapy in neuroblastoma such as *MYCN* amplification, TRKB signaling, or loss of p53 expression.[274,308]

MYCN-amplified tumors were found to possess a population of cells with CSC characteristics that was enriched during prolonged drug selection. Treatment with the histone deacetylase (HDAC) inhibitor vorinostat led to histone acetylation and increased the sensitivity of these cells to chemotherapy, with loss of their stemness properties and downregulation of stemlike marker genes.[309]

Acquired Resistance to Targeted Therapies

The dissection of the cancer genome that has resulted in the identification of targetable oncogenic drivers has propelled personalized medicine protocols aimed at treating subsets of patients whose tumors harbor sensitizing mutations. Although pediatric tumors have a relatively silent mutational landscape compared with adult tumors, targeted agents are being used in several cancers, including neuroblastoma. These agents include small-molecule inhibitors of ALK, TRKB, aurora kinase, and PI3K/mTOR, to name a few. Targeted therapies can induce impressive clinical responses, but relapse due to acquired resistance is a major challenge. Several mechanisms lead to acquired resistance to targeted agents: acquisition of secondary mutations or amplification of the drug target itself, activation of alternative or downstream signaling pathways, and changes in drug efflux or bioavailability (reviewed in reference 310).[310] Secondary mutations in the target gene such as gatekeeper mutations preserve pathway activity and confer resistance by interfering with drug binding. Engagement of alternative receptor–mediated pathways has also been reported as causing resistance. Resistance to targeted therapy can also occur through nongenetic mechanisms, such as a reversible drug-tolerant state in a subpopulation of cells that is maintained by a chromatin modification, implicating an epigenetic basis of drug resistance.[311] Another mechanism involves transdifferentiation or histologic transformation with epithelial to mesenchymal transition in the absence of any known genetic mechanism.[312]

Tumor Angiogenesis

Neuroblastoma is characterized by prominent angiogenesis, and neuroblastoma cells have been shown to induce angiogenesis in the chick embryo chorioallantoic membrane assay.[313] Increased tumor vascularity and microvascular proliferation is correlated with widely disseminated disease, MYCN amplification, unfavorable histology, and a poor outcome.[314-316] Such aggressive tumors are associated with high expression of VEGF, basic fibroblastic growth factor, and platelet-derived growth factor A[299,314] and integrins, which are markers of active angiogenesis.[317] The presence of angiogenesis appears to be influenced by the cellular composition of the tumor in that in highly aggressive stroma-poor neuroblastoma, angiogenesis is present as a result of the secretion of angiogenic stimulators, whereas in stroma-rich tumors, numerous angiogenic inhibitors secreted by Schwann cells appear to maintain the inhibitory phenotype.[318] The Schwann cells in neuroblastoma tumors have been shown to have very low tumor vascularity with production of angiogenesis inhibitors, such as tissue inhibitor of matrix metalloproteinase–2 (TIMP-2), pigment epithelium-derived factor, and SPARC (secreted protein acidic and rich in cysteine), a calcium-binding matricellular glycoprotein.[117,314,319] SPARC expression has been found to be inversely correlated with the degree of malignant progression in neuroblastoma tumors, and neutralizing SPARC with antibodies reverses the antiangiogenic activity of Schwann cell–conditioned media.[319]

Metastasis

Metalloproteinases such as matrix metalloproteinase–9 (MMP9), along with CD44 and NM23-H1, which regulate tumor cell adhesion and migration, may play a role in metastasis.[320-322] Overexpression of MMP2 and MMP9 is associated with tumor invasion and metastasis in many types of cancer, whereas inhibitors of MMPs have been shown to suppress tumor invasion and angiogenesis. An association between increased levels of MMP2 and MMP9 and advanced-stage tumors has been observed in neuroblastoma. Caspase-8 has also been shown to be a metastasis suppressor gene.[323] Decreased caspase-8 expression has been shown to occur during the establishment of neuroblastoma metastases in vivo, and reconstitution of caspase-8 expression in deficient neuroblastoma cells suppressed these metastases. Caspase-8 selectively potentiated apoptosis in metastasizing cells, and loss of caspase-8 allowed cellular survival in the stromal microenvironment and promoted metastases.[323,324] In the TH-MYCN mouse model of neuroblastoma, caspase-8 was associated with increased metastasis, specifically to the bone marrow, possibly caused by upregulation of genes involved in epithelial-mesenchymal transition (EMT), decreased cell adhesion, and increased fibrosis.[325]

PATHOLOGY

Neuroblastomas arise from primitive sympathetic precursors of the neural crest and belong to the family of small round blue cell tumors. The histopathology of the tumor cells correlates with stages of sympathetic nervous system development. Tumors are composed of small blue round cells that are uniformly sized and contain dense, hyperchromatic nuclei and scant cytoplasm. Surrounding the neuroblasts is stroma, known as Schwannian stroma. A typical feature of neuroblastoma is the presence of neuropil, which is made up of neuritic processes and is found in the majority of neuroblastomas. One of the pathognomonic features of neuroblastoma is the Homer-Wright pseudorosette, a collection of neuroblasts surrounding areas of neuropil, which occurs in up to half of cases (15% to 50%; Fig. 54-4, *A*).[326]

Neuroblastoma manifests as a spectrum of three histologic patterns ranging from neuroblastoma to ganglioneuroblastoma to ganglioneuroma, based on the degree of tumor cell differentiation. Neuroblastomas are composed of mostly small immature blue round cells with scanty cytoplasm, little evidence of differentiation, and high mitotic activity. Ganglioneuroblastomas are tumors with differentiated ganglion cells admixed with neuroblastic tissue. These tumors may vary from predominantly neuroblastic with rare ganglion cells to predominantly maturing cells with rare undifferentiated components, such as neuroblastic cells. If less than 50% of the cells are maturing cells, the tumor is termed a “maturing neuroblastoma,” and if more than 50% of the cells are maturing cells, it is termed a “ganglioneuroblastoma.” Ganglioneuroblastomas can also be focal or diffuse, and both types can exist within a single tumor. Two forms of ganglioneuroblastoma exist: (1) the intermixed variety, in which cells in various stages of differentiation are interspersed with small nests of neuroblasts, predicting a good outcome, and (2) the nodular type, in which hemorrhagic areas and macroscopic nodules are present, which is associated with a worse prognosis. Ganglioneuromas are fully differentiated tumors consisting entirely of maturing ganglion cells, neuropil Schwannian stroma, and nerve fibers.[327,328]

Primary histologic diagnosis may be enabled by hematoxylin and eosin staining and light microscopy. Other techniques also help distinguish neuroblastomas from other small round blue cell tumors of childhood, such as immunohistochemistry with use of antibodies for neural markers, such as neurofilament protein, synaptophysin, neuron-specific enolase, ganglioside GD2, chromogranin A, and tyrosine hydroxylase. Electron microscopy studies may exhibit dense core-membrane–bound neurosecretory granules and microfilaments and parallel arrays of microtubules within the neuropil.[329]

Tumor histology in neuroblastoma has traditionally been determined by the Shimada classification system.[330] Tumors are classified as favorable or unfavorable based on three features: amount of stroma, degree of neuroblastic cell differentiation, and the mitosis-karyorrhexis index (MKI; the percentage of tumor cells in mitosis versus karyorrhexis). This system had one drawback in that it was age-linked, and age itself is a strong independent prognostic feature in neuroblastoma. The Joshi system was simpler in that it examined the presence of calcification and mitotic rate (less than or equal to 10 mitoses per 10 high-power fields) and was designed to be independent of age and stage; however, it did not have the same prognostic power as the Shimada system.[331] Subsequently a unified classification, the International Neuroblastoma Pathology Classification (INPC), was established in 1999[332] and revised in 2003.[333] This classification schema was formulated on the basis of the natural history of neuroblastoma of involution and maturation as described by Beckwith and Perrin (1963).[27] In other words, it is based on the age-dependent normal ranges of morphologic features such as Schwannian stroma, degree of neuroblastic differentiation, and MKI and seeks to divide neuroblastic tumors into those with favorable and unfavorable histology (Fig. 54-4, *B*).[334]

The INPC has four main morphologic categories (Table 54-2).The first category is neuroblastoma (Schwannian-stroma poor), which is a tumor with nests of neuroblastic cells interspersed with little or minimal stroma. There are three subtypes, based on grade of differentiation: (a) undifferentiated, (b) poorly differentiated (some neuropil and <5% of cells exhibiting differentiation), and (c) differentiating (abundant neuropil and >5% of cells showing differentiation toward ganglion cells).

MKI, Mitosis-karyorrhexis index.

[*] Subtypes of neuroblastoma are described in detail elsewhere.[332]

[†] Rare subtype, especially diagnosed in this age group. Further investigation and analysis are required.

[‡] Prognostic grouping for these tumor categories is not related to patient age.

The second category is ganglioneuroblastoma, intermixed (Schwannian stroma-rich), which is a tumor that contains well-defined microscopic nests of neuroblastic cells intermixed in ganglioneuromatous stroma. The nests are composed of neuroblastic cells in various stages of differentiation, but they are primarily composed of differentiating neuroblasts and maturing ganglion cells in a background of neuropil. The third category is ganglioneuroblastoma, nodular (composite Schwannian stroma-rich/stroma-dominant and stroma-poor). This tumor is composed of biologically different clones, an aggressive clone composed of grossly visible, hemorrhagic neuroblastic nodules (stroma-poor component), and a nonaggressive clone comprising ganglioneuroblastoma, intermixed (stroma-rich component), or with ganglioneuroma (stroma-dominant component). The fourth category is ganglioneuroma (Schwannian-stroma–dominant), of which there are two subtypes, maturing and mature. The maturing subtype is composed predominantly of ganglioneuromatous stroma with scattered differentiating neuroblasts or maturing ganglion cells, as well as fully mature ganglion cells. The mature subtype is composed of ganglion cells and Schwannian stroma.

In the new and revised International Neuroblastoma Risk Group (INRG) classification schema, tumor histology will be classified independent of age and will primarily be based on degree of differentiation and the MKI.

CLINICAL PRESENTATION

Neuroblastomas are tumors of sympathetic nervous system and can arise anywhere along the sympathetic chain or in any sympathetic ganglia. Most primary tumors occur in the abdomen (65%), and half of abdominal tumors occur in the adrenal gland. Other common sites of disease origin include the chest, neck, and pelvis, although rarely a primary tumor cannot be found. Because the sites of origin of neuroblastoma are so diverse, the signs and symptoms of disease at presentation vary widely and depend on both the location of the primary tumor and the degree of disease dissemination.

Localized Disease

Approximately 40% of patients present with localized disease.[335] Primary abdominal disease can present as an asymptomatic abdominal mass or with abdominal pain and fullness. Symptoms of obstruction can occasionally be seen, along with renin-mediated hypertension caused by compression of the renal vasculature.[336] Abdominal or pelvic tumors can also occasionally cause compression of lower extremity venous and lymphatic drainage, leading to lower extremity and scrotal swelling. Rarely abdominal tumors spontaneously hemorrhage, and patients with such hemorrhage present with a sudden, dramatic enlargement of an abdominal mass with increased distension and pain. Lower thoracic tumors are usually identified incidentally when a chest radiograph is obtained for unrelated reasons. Occasionally large thoracic tumors are associated with mechanical obstruction and resultant superior vena cava syndrome. Upper thoracic or cervical tumors may cause Horner syndrome.[337] Congenital tumors arising in this site can also cause hematochromia of the iris as a result of decreased pigmentation of the iris on the affected side.[338] Neuroblastoma arising from the paraspinal ganglia in the chest, abdomen, or pelvis can grow through the intervertebral foramina and compress the spinal cord. Patients may be asymptomatic or present with pain or neurologic deficits resulting from spinal cord compression, which requires emergent treatment as detailed later in this chapter.

Metastatic Disease

Metastatic spread of neuroblastoma occurs through the lymphatics or hematogenously. Regional lymph node metastases are seen in one third of patients with apparently localized tumors, and half of patients present with hematogenous metastases.[335] Hematogenous spread occurs most frequently to the bone, bone marrow, and/or liver; rarely, metastasis to the lungs and brain occurs, usually at relapse rather than at presentation. Classic signs of metastatic neuroblastoma include proptosis and periorbital ecchymoses (commonly referred to as "raccoon eyes") due to tumor infiltration of the periorbital bones. Patients also frequently present with limping and irritability due to bone pain from bone and bone marrow disease, as well as nonspecific symptoms including fever and failure to thrive. The presence of fever is usually associated with extensive bone metastases. Signs and symptoms of bone marrow replacement are also sometimes seen—most frequently pallor (which may also be caused by bleeding within the primary tumor), as well as bruising and increased risk of infection as a result of a low white blood cell count.[339]

Stage 4S Neuroblastoma

Stage 4S (S = special) is a unique presentation of neuroblastoma seen in infants; it was originally described by D'Angio, Evans, and Koop in 1971.[340] Infants with stage 4S neuroblastoma often present with massive hepatomegaly caused by diffuse liver metastases and nontender, bluish subcutaneous nodules as a result of skin nodules. Stage 4S disease accounts for 7% to 12% of neuroblastoma diagnoses and is historically defined as the presence of a small, localized primary tumor with metastases isolated to the liver, skin, and/or bone marrow in an infant younger than 12 months.[341] This special neuroblastoma often spontaneously regresses, although infants younger than 2 months can present with respiratory compromise due to a rapidly enlarging liver and may require cancer-directed treatment.[342] Based on an analysis of a large cohort of international patients diagnosed with neuroblastoma between 1990 and 2002, the INRG Task Force has extended the definition of 4S neuroblastoma to include patients up to the age of 18 months and those with primary tumors crossing the midline.[343]

Paraneoplastic Syndromes

Opsoclonus-myoclonus syndrome (OMS) and vasoactive intestinal peptide syndrome, which are well-described paraneoplastic syndromes associated with neuroblastoma, are detailed in this section, along with a newly described syndrome known as rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation (ROHHAD). Patients with these syndromes usually have localized tumors with favorable biology, perhaps because the syndrome causes early detection of tumor or, more likely, because of a correlation between the syndrome and the tumor biology.

OMS is observed in 2% to 3% of children with neuroblastoma[344] and is usually diagnosed between the age of 1 and 3 years.[345] It is often referred to as "dancing eyes, dancing feet syndrome" and is characterized by the acute onset of rapid eye movements, ataxia, myoclonic jerking of the limbs and trunk, and behavioral disturbances.[345] Although children with neuroblastoma and OMS generally have favorable tumor prognostic features and a high survival rate,[346-348] 70% to 80% experience long-term neurologic sequelae that can include global developmental delay, speech and/or motor delay, behavioral disturbances, and cognitive deficits that can seriously affect quality of life.[344,347,349,350] OMS in children is associated with neuroblastoma more than half of the time.[345] After exclusion of CNS pathology, all children with OMS should be evaluated for neuroblastoma with imaging of their chest and abdomen, an iodine 123–metaiodobenzylguanadine (MIBG) scan, and urine catecholamines.[351] Traditional methods to detect neuroblastoma may be insensitive in patients with OMS,[352,353] and therefore high-resolution computed tomography (CT) or magnetic resonance imaging (MRI) of the chest and abdomen should be considered, even in patients with negative catecholamines or negative results of an MIBG scan, to screen for small tumors.

OMS and its sequelae are thought to be immune mediated and are likely caused by the presence of an antineural antibody that cross-reacts with a common antigen on both neuroblastoma and normal nervous system tissue.[345] Improvement in symptoms can be seen after tumor removal in some cases, but generally immunosuppression with glucocorticoids or adrenocorticotropic hormone is used to relieve acute symptoms.[345,347,354] However more than 80% of patients will have a relapse of symptoms with steroid weaning or in association with a viral syndrome,[351] and more than half of patients will need prolonged steroid treatment, necessitating additional treatment approaches. Intravenous immune globulin has also been used in the treatment of OMS, either with or without steroids, with varying success.[355,356] Case reports have shown efficacy of other immunomodulating strategies including plasmapheresis, rituximab, and mycophenolate.[357-361] Although often effective in treating acute symptoms, none of these treatments has been consistently correlated with improved long-term outcome. Interestingly, a report from the Pediatric Oncology Group (POG) suggested that patients who received chemotherapy to treat their neuroblastoma had a more favorable neurologic outcome.[344] This benefit may be due to the immunosuppressive effects of chemotherapy or to less severe activation of the immune system in patients with more advanced stages of tumor.[345] The same benefit was not observed in a similar review performed by the Children's Cancer Group (CCG),[347] and the benefit of chemotherapy for the treatment of OMS needs to be investigated further. The COG recently conducted a trial for OMS in which patients with low-risk neuroblastoma who would not otherwise receive chemotherapy were treated with cyclophosphamide in addition to steroids. Long-term outcome of these patients compared with historic control subjects should provide insight regarding the role of chemotherapy for the treatment of OMS.

Further investigation is needed to determine the best treatment approach for OMS.[362] Regardless of treatment, physicians caring for patients with OMS should anticipate long-term neurologic abnormalities and use early intervention to help minimize these deficits.

Tumor secretion of vasoactive intestinal peptide can cause a syndrome of chronic watery diarrhea and failure to thrive. Most tumors secreting vasoactive intestinal peptide are histologically mature. Surgical removal of the tumor usually results in complete resolution of symptoms.[363]

ROHHAD syndrome is characterized by rapid-onset obesity, hypothalamic dysfunction, hypoventilation, and autonomic dysregulation.[364] Tumors of neural crest origin have been found in more than one third of cases[364,365] and are usually differentiated (ganglioneuromas or ganglioneuroblastomas).[366] ROHHAD syndrome most commonly affects otherwise normal children between 2 and 4 years of age and typically presents first with rapid weight gain and obesity followed at varying time intervals by autonomic dysfunction and hypoventilation. The prognosis is poor, and at least 25% of children die because of respiratory failure. A genetic cause has been suggested because of the constellation and consistency of symptoms and the reported occurrence in siblings,[366] but several candidate genes (including *PHOX2B, ASCL1* [achaete-scute family bHLH transcription factor–1], *NTRK2 [TRKB]*, and *BDNF*) have been sequenced in affected patients and have not been informative.[364,366] Monozygotic twins discordant for ROHHAD have recently been reported,[367] although this in itself should not preclude a genetic cause because modifier genes or epigenetic variation may play a role in the variable phenotype. Because of the association with neuroblastic tumors and the finding of extensive infiltrates of lymphocytes and histiocytes in the hypothalamus of some patients,[368,369,370] a paraneoplastic cause has been postulated. Immune-modulating agents including intravenous immunoglobulin, rituximab, and cyclophosphamide have been tried in small series of patients with varying success,[367,370a] and collaborative studies are needed to determine the cause of this rare disorder. Surveillance for tumors in patients with this constellation of features is recommended.

DIAGNOSIS AND EVALUATION

Diagnosis

The diagnosis of neuroblastoma is usually established from histopathologic evaluation of primary tumor tissue.[371] In most cases, especially if features of neuronal differentiation are present, a tissue diagnosis of neuroblastoma can be made on the basis of conventional hematoxylin and eosin staining. However, in cases in which there is little differentiation and only small round blue cells are evident, immunohistochemical staining for neuron-specific enolase, chromogranin A, and/or synaptophysin, as well as cytogenetic and molecular analysis, can help differentiate neuroblastoma from other small round blue cell tumors of childhood.[357-359]

In addition to establishing the diagnosis, primary tumor material is essential for risk stratification and prognosis, particularly in children younger than 18 months with locoregional or metastatic spread. In cases in which primary tumor tissue cannot be obtained safely, the diagnosis of neuroblastoma can also be made by demonstrating unequivocal neuroblastoma cells in a bone marrow aspirate or biopsy in conjunction with increased urinary catecholamines. Urinary catecholamine metabolites are increased in 90% to 95% of neuroblastomas using sensitive detection techniques such as high-performance liquid chromatography[372,373] and can be helpful in establishing a diagnosis, as well as in monitoring disease activity and response to therapy in patients who are known to excrete the metabolites. In sympathetic cells the catecholamine precursor 3,4-dihydroxyphenylalanine (DOPA) is converted to dopamine by DOPA decarboxylase, which is converted to norepinephrine and then to epinephrine by the enzyme phenylethanolamine-N-methyltransferase, which is not present in neuroblastoma cells.[374] Instead the enzymes catechol-O-methyltransferase and monoamine oxidase convert DOPA and dopamine to homovanillic acid and norepinephrine and epinephrine to vanillylmandelic acid, both of which are inactive metabolites that are excreted in the urine. Both urinary homovanillic acid and vanillylmandelic acid should be measured for diagnostic purposes. For undifferentiated tumors, urinary dopamine may also be useful.[371] Despite this catecholamine production, symptoms of catecholamine excess such as hypertension, flushing, and sweating are rarely seen in persons with neuroblastoma, likely because of the relatively low concentrations of active catecholamines in the circulation.

Clinical Disease Assessment

The primary tumor and the extent of disease should be evaluated using imaging techniques both at diagnosis and to evaluate response to treatment. Either CT or MRI are routinely used to evaluate the extent and origin of the primary tumor, as well as possible solid organ metastases.[375] CT is more widely available and can rapidly capture images, reducing the need for sedation, but it is associated with substantial radiation exposure. Ionizing radiation is not used to perform MRI but it has a longer imaging acquisition time, making sedation necessary in most young children. Currently no consensus exists with regard to which imaging technique is optimal for evaluating tumors and metastases in the abdomen, pelvis, or mediastinum. Availability and clinical factors, including the risks of sedation, should be taken into account. MRI is preferred for assessing paraspinal lesions, particularly those with possible intraextension and spinal cord impingement. Although abdominal ultrasonography is not as useful for assessing tumor volume and anatomy, it may be useful as a noninvasive method for following tumor response or surveying for disease relapse. Brain imaging is only recommended if clinically indicated by symptoms or examination.

Bone and bone marrow should also be evaluated by imaging to look for the presence and extent of metastatic disease. MIBG is a norepinephrine analogue that is selectively concentrated in more than 90% to 95% of neuroblastomas and can be combined with either the iodine 131 or ^{123}I isotopes for scanning purposes. MIBG scintigraphy is highly sensitive and specific for detecting osteomedullary disease and can also be used to assess the primary tumor, as well as occult soft tissue disease (Fig. 54-5). The ^{123}I isotope provides enhanced image resolution and is the isotope of choice when it is available. MIBG scans are essential for the initial staging of neuroblastoma and should be performed prior to primary tumor resection. International guidelines are available for patient preparation, radiotracer administration, and imaging techniques.[376] A bone scan using technetium 99m–diphosphonate scintigraphy is a relatively sensitive but less specific method to detect bony metastases in patients with neuroblastoma. Bone scans are recommended in cases in which the primary tumor is not MIBG avid, or in cases in which tumor uptake of MIBG cannot be confirmed (i.e., in cases in which the primary tumor is removed prior to imaging for metastatic disease).[375] Fluorine 18–labeled deoxyglucose positron emission tomography (FDG-PET) can also be used to evaluate metastatic disease in persons with neuroblastoma.[377-379] Its sensitivity and specificity in comparison with MIBG scintigraphy is still being evaluated, with studies suggesting that MIBG is more sensitive than FDG-PET for the detection of bone lesions and skull-based lesions, and that FDG-PET is more sensitive than MIBG for the detection of small soft tissue tumors and nodal metastases.[380] The routine use of FDG-PET is not currently recommended, but it may be a helpful tool to follow-up patients with metastatic disease who do not have MIBG-avid tumors.

Bone marrow aspirates and biopsies from both iliac crests are recommended to assess for the presence of bone marrow disease using standard histologic analysis.[371,381] Both immunocytochemical and polymerase chain reaction–based technologies can be used to increase sensitivity of marrow detection. Immunocytochemical analysis of bone marrow aspirates with monoclonal antibodies directed against neural-specific antigens (e.g., GD2 and NCAM, neural cell adhesion molecule) increases the sensitivity of detecting marrow involvement to 1:100,000 nucleated cells.[382] Reverse-transcriptase polymerase chain reaction methodologies that target the expression of neuroblastoma-specific messages such as tyrosine hydroxylase, protein gene product 9.5, or GD2 synthase can enhance sensitivity further.[383-388] However, the clinical and prognostic significance of this enhanced detection, remains to be determined, and these studies are generally only recommended within the context of a clinical study.

Staging

The International Neuroblastoma Staging System (INSS) was established in the 1990s to replace three major staging systems used throughout the world in an effort to provide international uniformity so that clinical trials and biology studies performed by different groups in different countries could be compared.[371,381] The INSS (Table 54-3) is largely based on the surgical assessments of a patient at diagnosis and has been used nationally and internationally for more than 20 years. However, because surgical approaches are not uniform, the INSS stage for patients with locoregional disease can vary considerably depending on the degree of initial tumor resection, making comparison of clinical trials conducted in different parts of the world difficult. To address this problem, the INRG Task Force developed a new staging system based on tumor imaging rather than extent of surgical resection.[389] This staging system (known as the INRG staging system) uses radiologic characteristics of the primary tumor to predict surgical risk and resectability (Tables 54-4 and 54-5).[390] Using this approach, in INRG staging, locoregional disease is classified as stage L1 or L2 on the basis of whether the tumor is locally invasive by imaging at the time of diagnosis. Stage M indicates metastatic disease that is assessed in the same

TABLE 54-3 International Neuroblastoma Staging System[371,381]

Stage	Description
1	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with the primary tumor may be positive)
2A	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically
2B	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor; enlarged contralateral lymph nodes must be negative microscopically
3	Unresectable unilateral tumor infiltrating across the midline,* with or without regional lymph node involvement; *or* localized unilateral tumor with contralateral regional lymph node involvement; *or* midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement
4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin and/or other organs (except as defined for stage 4S)
4S	Localized primary tumor (as defined for stage 1, 2A, or 2B), with dissemination limited to skin, liver and/or bone marrow† (limited to infants younger than 1 year of age)

Multifocal primary tumors (i.e., bilateral adrenal primary tumors) should be staged according to the greatest extent of disease, as previously defined, followed by a subscript "M" (e.g., 3_M).

*The midline is defined as the vertebral column. Tumors originating on one side and "crossing the midline" must infiltrate to or beyond the opposite side of the vertebral column.

†Marrow involvement in stage 4S should be minimal, that is, less than 10% of total nucleated cells identified as malignant on bone marrow biopsy or aspirate. More extensive marrow involvement would be considered to be stage 4. The metaiodobenzylguanidine scan (if done) should be negative in the marrow.

way it was assessed by INSS criteria, via both imaging and pathology.

The INRG system also differs from the INSS system in that the midline and lymph node status are not included in the staging criteria. In addition, INRG stage MS includes patients up to 18 months of age and those with L2 tumors, whereas INSS stage 4S has an upper age limit of 12 months and includes only patients with stage 1 or 2 primary tumors.

Because imaging can be retrospectively reviewed, the INRG staging system should provide data that are more uniform than the INSS system. The INRG staging system is currently used in Europe and will be adopted into the COG studies as well.

TABLE 54-4 Image-defined Risk Factors in Neuroblastic Tumors[375,593]

Anatomic Region	Description
Multiple body compartments	Ipsilateral tumor extension within two body compartments
Neck	Tumor encasing carotid artery, vertebral artery, and/or jugular vein Tumor extending to skull base Tumor compressing trachea
Cervicothoracic junction	Tumor encasing brachial plexus roots Tumor encasing subclavian vessels, vertebral artery, and/or carotid artery Tumor compressing trachea
Thorax	Tumor encasing aorta and/or major branches Tumor compressing trachea and/or principal bronchi Lower mediastinal tumor infiltrating costovertebral junction between T9 and T12 vertebral levels
Thoracoabdominal junction	Tumor encasing aorta and/or vena cava
Abdomen and pelvis	Tumor infiltrating porta hepatis and/or hepatoduodenal ligament Tumor encasing branches of the superior mesenteric artery at the mesenteric root Tumor encasing the origin of the celiac axis and/or the origin of the superior mesenteric artery Tumor invading one or both renal pedicles Tumor encasing the aorta and/or vena cava Tumor encasing the iliac vessels Pelvic tumor crossing the sciatic notch
Intraspinal tumor extension	Intraspinal tumor extension provided that more than one third of the spinal canal in the axial plane is invaded, the perimedullary leptomeningeal spaces are not visible, or the spinal cord signal intensity is abnormal
Infiltration of adjacent organs and structures	Pericardium, diaphragm, kidney, liver, duodenopancreatic block, and mesentery

TABLE 54-5 International Neuroblastoma Risk Group Staging System[389]

Stage	Description
L1	Localized tumor not involving vital structures as defined by the list of image-defined risk factors and confined to one body compartment
L2	Locoregional tumor with the presence of one or more image-defined risk factors
M	Distant metastatic disease (except stage MS)
MS	Metastatic disease in children younger than 18 months with metastases confined to skin, liver, and/or bone marrow

Patients with multifocal primary tumors should be staged according to the greatest extent of disease as defined in the table.

RISK STRATIFICATION

Neuroblastoma is a tumor in which biologic factors are consistently used to influence disease risk stratification and treatment. In 1998 the COG established a risk-stratification system that stratifies patients into low-, intermediate-, or high-risk categories based on prognostic features including age at diagnosis, stage, tumor histology, DNA index (ploidy), and MYCN amplification status (Table 54-6). Treatment recommendations are based on this risk grouping, as described in the next section, and prognosis is distinct for each risk group (Fig. 54-6).

In an effort to unify risk stratification internationally and facilitate comparison of clinical trials performed in different parts of the world, the INRG Task Force was formed with representatives from the major pediatric cooperative groups. The INRG Task Force retrospectively analyzed the prognostic effect of 13 variables in a cohort of 8800 patients diagnosed with neuroblastoma between 1990 and 2002 with respect to EFS. Based on these analyses, a consensus INRG classification scheme was created using the most statistically significant and clinically relevant factors, which include INRG stage, age, histology, grade of tumor differentiation, MYCN and 11q status, and tumor ploidy (Table 54-7).[343] The significance of the risk factors used in both the INRG and COG risk stratification systems is described later.

Clinical Variables

Age is an important prognostic factor in neuroblastoma. Traditionally it was thought that infants (those younger than 1 year or 365 days of age) had a more favorable outcome, whereas children older than 1 year had a

much more dismal outcome, especially those with metastatic disease at diagnosis.[391,392] However, recent studies of a large series of cases have demonstrated that age is a continuous prognostic variable in neuroblastoma, and 18 months has been identified as the age under which patients with stage 3 and 4 disease share the same favorable outlook as those younger than 1 year of age (Fig. 54-7).[3,110,393] Whether children aged between 12 and 18 months who have advanced stage disease but otherwise favorable biologic features can be cured with less aggressive therapy is currently under investigation. Fewer than 5% of cases of neuroblastoma are diagnosed in children older than 10 years. Experience suggests that older patients with high-risk–type disease can have a more indolent course but ultimately a dismal outcome, implicating a unique tumor biology.[394-397] Age older than 10 years is not currently used in risk stratification but may be in the future when the biology is more clearly understood.

Stage has always been considered an important prognostic factor, with low stage or localized disease having a better outcome than high stage or metastatic disease; the overall prognosis for patients with stage 1, 2, and 4S disease is 80% to 90%, whereas patients with disease between stages 3 and 4 have a 2-year survival rate of 20% to 40%.[374] As described previously, the INRG staging system, which determines local-regional disease extent based on image-defined risk factors rather than surgical risk factors, is in the process of being adopted internationally.

Pathologic features are also used to classify neuroblastomas. The Shimada classification divides tumors as having "favorable" and "unfavorable" histology by incorporating age with tumor differentiation, MKI, and Schwannian stroma.[330] However, because age itself is a strong independent prognostic variable, new classification systems such as the INRG examine MKI and differentiation as independent variables, along with established clinical and biologic variables.

Biologic Variables

Biologic factors currently used for neuroblastoma risk stratification include *MYCN* copy number by fluorescence in situ hybridization,[397a] DNA ploidy by flow cytometry,[108] and tumor histology using the INPC.[332] *MYCN* amplification automatically stratifies children into the high-risk category in a majority of cases, except for completely resected INSS tumors, which remains controversial. DNA index or ploidy is considered prognostic

TABLE 54-7 International Neuroblastoma Risk Group Consensus Pretreatment Classification[343]

INRG Stage	Age (mo)	Histologic Category	Grade of Tumor Differentiation	MYCN	11q Aberration	Ploidy	Pretreatment Risk Group
L1/L2		GN maturing; GNB intermixed					A Very low
L1		Any, except GN maturing or GNB intermixed		NA			B Very low

in children up to 18 months of age.[110] Neuroblastoma tumors are classified as diploid (DNA index [DI] = 1) and hyperdiploid (DI > 1). In the COG schema, a DI of 1 would stratify a patient to the high-risk group if the patient was between 12 and 18 months of age with stage 4 disease, regardless of *MYCN* amplification status or histology. Diploid DNA content in infants (<12 months) with *MYCN* nonamplified, stage 4S disease will signify intermediate risk, regardless of tumor histology.

Other genetic features such as evaluation for LOH of 1p36 and 11q23[261] were used to stratify therapy in prior studies and could be important for stratification of non–high-risk patients with neuroblastoma. In patients with neuroblastoma whose tumors did not have MYCN amplification, the prognostic impact of the three most common segmental chromosomal alterations—1p deletion, 11q deletion, and/or 17q gain—was studied.[107] Segmental chromosomal anomalies were more frequent in children older than 18 months and with stage 4 disease. In multivariate analysis, the presence of a segmental genotype significantly correlated with a poorer EFS, although age and stage were still more significant; therefore the utility of such a segmental genomic profile for prognostic risk assessment is questionable, given that age and stage were still more significant in this study ($P < .0001$ and $P = .0002$, respectively, vs. $P = .01$ for the segmental genotype).[107]

APPROACH TO TREATMENT

The modalities used in the treatment of neuroblastoma include surgery, chemotherapy, radiotherapy, and biotherapy, as well as observation alone in a small subset of patients. The determination of treatment is largely based on prognostic factors and subsequent risk group assignment, as previously described. A major goal of ongoing neuroblastoma clinical trials is to prospectively validate the existing risk group assignments, as well as to evaluate newer prognostic markers for future refinement of risk stratification and treatment assignment. The general principles of therapy for each of the current risk groups are detailed below.

Treatment of Low-Risk Disease

Low-risk neuroblastoma is defined as INSS stage 1 disease in patients of any age, INSS stage 2 in infants 365 days of age or older with any MYCN status and histology, INSS stage 2 in children older than 365 days with MYCN of any status and favorable histology, and INSS stage 4S MYCN—not amplified, favorable histology, and hyperdiploid. For patients with INSS stage 1 disease, surgical resection is almost always the only treatment required, and these patients have an excellent OS rate. The COG study P961 prospectively evaluated 915 eligible patients with low-risk neuroblastoma. The 453 patients with INSS stage 1 disease had a 5-year EFS and OS of 93% ± 2% and 99% ± 1% with surgery as their primary treatment, which is consistent with findings of previous studies.[398] The same COG study showed that chemotherapy can be omitted for most patients who have biologically favorable but incompletely resected localized tumors (INSS stage 2A and 2B). Patients with asymptomatic INSS stage 2 disease were observed after surgery and had 5-year EFS and OS of 87% ± 2% and 96% ± 1%, respectively. The EFS was significantly better for patients with stage 2A disease compared with stage 2B disease (92% ± 3% and 85% ± 3%; $P = .0321$), but the OS did not differ. The majority of patients with INSS stage 2B disease had unfavorable histology and/or diploid tumors, which independently had a significant impact on EFS and OS. Similar results were published by the International Society of Pediatric Oncology neuroblastoma group.[399] For low-risk disease, chemotherapy should only be used in cases in which the tumor is causing organ- or life-threatening symptoms or in cases of recurrent of progressive disease not amenable to surgery. Although disease recurrence is rarely seen, it usually occurs within a year of diagnosis, and the majority of recurrences are local.[400-402] Local recurrences in low-risk patients can usually be managed with second surgeries. Metastatic recurrences are rare but are often salvageable with more intensive systemic therapy.

Neuroblastoma is known to have one of the highest rates of spontaneous regression among malignant tumors, which has been well documented in patients with stage 4S disease.[403] Data from mass screening studies in Japan show a two- to threefold higher incidence of neuroblastoma in areas with screening programs.[404] This increase in the rate of diagnosis supports the hypothesis that a subset of non–stage 4S neuroblastomas in young infants can undergo spontaneous regression as well. The German Society of Pediatric Oncology and Hematology reported a prospective trial supporting this hypothesis.[405] Ninety-three infants with localized neuroblastoma were observed without use of surgery or chemotherapy. Spontaneous regression was seen in 44 of the 93 infants (47%), and 17 infants had a complete regression. The 3-year EFS (56% ± 5%) was low because approximately half of the infants required an intervention, but the overall survival remained excellent (99% ± 1%). This study included patients with locally invasive disease and any tumor biology except for MYCN amplification. The COG recently completed an observation study for perinatally detected adrenal tumors to further explore the hypothesis of spontaneous regression in young infants with localized tumors.[406] This study had more restricted eligibility than did the German study, limiting enrollment to patients 6 months of age or younger with tumors limited to the adrenal gland, but biopsies were not performed to confirm diagnosis and determine tumor biology. Parents could choose observation or immediate surgical resection at enrollment. Eighty-seven eligible patients were enrolled, and for 83 patients, the parents elected observation. For the observation arm, 56 patients completed observation and 27 discontinued observation (13 were lost to follow-up). The majority of the patients who completed observation had a decrease in the volume of their adrenal mass, and 27 patients (48%) had no residual mass at the end of the observation period. Sixteen observation patients had surgery (one at the end of the observation period); 10 patients had neuroblastoma, 2 had low-grade adrenal cortical neoplasms, 2 had adrenal hemorrhages, and 2 had extralobar pulmonary sequestrations. Nine of the patients with neuroblastoma underwent surgery as a result of progression, seven had INSS stage 1 disease, one had INSS stage 2B disease, and one had INSS stage 4S (neither of the latter two patients required further treatment). For the overall cohort, the 3-year EFS for a neuroblastoma event was 97.7% ± 2.2%, and the 3-year OS was 100%. The results of this study confirm that expectant observation results in excellent survival rates and spares surgery in a majority of infants with adrenal masses. The COG has plans to extend observation to all L1 tumors in infants in a future clinical trial.

The optimal treatment of the rare patient with *MYCN*-amplified, localized neuroblastoma is controversial. Most studies have demonstrated a worse outcome for patients with localized tumors with *MYCN* amplification. A CCG prospective analysis of 374 patients with Evans stage I and II disease showed that four of seven patients (four with stage I disease and three with stage II disease) who had MYCN amplification experienced a relapse (in three cases, the disease was metastatic) between 2 and 22 months from diagnosis, and three of these patients died as a result of disease progression.[400] A POG analysis of 329 patients with stage A neuroblastoma showed that 4 of 11 patients with MYCN amplification remained disease free 22 months to 68 months after initial surgery. Additional treatment of four of seven patients with recurrent disease was successful. In the COG P9641 study previously described, 10 patients with INSS stage 1 disease had MYCN amplification. Five-year EFS was 93% ± 2% and 70% ± 17%, and OS was 99% ± 1% and 80% ± 15% for MYCN nonamplified and MYCN-amplified tumors, respectively ($P < .001$).[398] Although these results clearly support a worse outcome for MYCN-amplified localized disease, they also show (based on a small sample size) that a subset of patients may achieve long-term remission with surgery alone.[401] A retrospective review of 600 patients (32 with MYCN-amplified tumors) who had localized neuroblastoma and were enrolled in a POG neuroblastoma biology study from 1990 to 1999 suggests that ploidy might be useful for further risk stratification of these rare patients. In this study ploidy was significantly correlated with outcome for patients with *MYCN*-amplified localized disease (7-year OS 87% + 9% for patients with hyperdiploid tumors vs. 38% + 12% for patients with diploid/hypodiploid tumors).[407] The same outcome was found in a retrospective analysis of the INRG database, which contains 2600 patients with low-stage neuroblastoma, known MYCN status, and available follow-up data. In this database 87 patients had low-stage disease with MYCN-amplified tumors, and they had a less favorable outcome compared with patients who had nonamplified tumors (5-year OS 72% ± 7% vs. 98% ± 1%).[408] As in the POG analysis, the outcome of patients with hyperdiploid tumors was significantly better than in patients with diploid tumors (5-year OS 94% ± 11% vs. 54% ± 15%). Further prospective evaluation is needed to determine a consensus treatment strategy for these patients.

Cord compression from intraspinal tumor extension can occur in children who otherwise would be considered low risk and is an oncologic emergency requiring rapid intervention. The choice of emergent therapy is somewhat controversial, with pediatric oncologists favoring chemotherapy and neurosurgeons favoring laminectomy with spinal cord decompression.[409] Retrospective analyses show similar neurologic outcomes for patients treated with chemotherapy versus laminectomy.[410-413] The severity of motor impairment at diagnosis seems to be the strongest predictor of short-term response to treatment and the development of long-term functional outcome. Studies have also shown that because of the young age of most of these patients, laminectomy can result in significant long-term orthopedic problems.[414] For these reasons, intermediate-risk–type chemotherapy is preferred in most cases for emergent treatment of spinal cord compression. Neurosurgery should be reserved for patients with rapid neurologic deterioration or those in whom worsening symptoms develop while they are receiving chemotherapy. Radiation therapy can also be used but is usually reserved for patients with progressive neurologic abnormalities despite chemotherapy and surgical decompression because of the long-term morbidity of spinal irradiation in infants and young children.[409]

Most patients with INSS stage 4S disease have favorable biologic features (single-copy MYCN, hyperdiploid, and favorable Shimada histology) and are categorized as having low-risk disease. The POG reviewed 110 patients with stage D(S) neuroblastoma diagnosed between 1987 and 1996 and found a 3-year OS rate of 85% ± 4% with a significantly worse prognosis for infants younger than 2 months of age or those with tumor cell diploidy, unfavorable histology, or *MYCN* amplification.[341] A report from the CCG showed similar results for 80 infants with a 5-year OS of 92%.[342] Patient with suspected INSS stage 4S neuroblastoma should undergo biopsy of the primary tumor or an accessible metastatic site (such as a subcutaneous nodule) to establish the diagnosis and to determine biologic features of the tumor. Patients with favorable biologic features usually do not require therapy and should be observed closely.[340] Resection of the primary tumor is not necessary to achieve an excellent outcome in these patients.[341] Patients with progressive or symptomatic disease and those who are too ill to undergo a biopsy at diagnosis are generally treated with moderately intensive chemotherapy, such as that currently recommended for intermediate-risk disease.[341,342] Patients with hepatomegaly that progresses despite chemotherapy and causes respiratory compromise are treated with small doses of radiation—450 to 600 cGy in 150-cGy fractions. The rare patient with INSS stage 4S disease who has unfavorable ploidy and/or histology tumors should be treated with intermediate-risk–type therapy. Patients with INSS stage 4S disease who have *MYCN* amplification should be treated with high-risk–type therapy.

Treatment of Intermediate-Risk Disease

The intermediate-risk classification group includes a wide spectrum of disease. The current approach to treatment utilizes a combination of moderate-dose multiagent chemotherapy and surgery with an expected OS of greater than 90%. The CCG 3881 study was one of the first to prospectively stratify patients according to risk group. In this study intermediate-risk patients (defined by MYCN status, age, histology, and ferritin level) were treated with moderately dose-intensive chemotherapy (cyclophosphamide, doxorubicin, cisplatin, and etoposide), along with local radiation for any gross residual disease after surgery. Patients who had favorable biology (i.e., MYCN that was not amplified, a favorable Shimada classification, and a low serum ferritin level) had an OS of 92% to 100% depending on stage, and infants with unfavorable features had an OS of 93%.[415,416] After this study, in the COG A3961 study, investigators attempted to reduce acute and long-term toxicity of the CCG regimen by substituting carboplatin for cisplatin and decreasing total cumulative doses of chemotherapy while maintaining dose intensity and eliminating radiation therapy in all patients except those with unresectable primary tumors and unfavorable biologic features at the end of chemotherapy. This study used the COG risk stratification described previously and enrolled 479 eligible patients between 1997 and 2005. Intermediate-risk neuroblastoma was defined as INSS stage 3 or 4 disease in an infant (<365 days of age) without MYCN amplification; stage 3 disease and favorable histopathologic features in a child (≥365 days of age); and stage 4S disease with unfavorable histopathologic features and/or a diploid DNA index. Patients received four to eight cycles of chemotherapy depending on risk factors. Among all patients, 3-year EFS and OS were 88% ± 2% and 96% ± 1%, proving that therapy could be substantially reduced for the majority of intermediate-risk patients.[417] The outcome for patients with INSS stage 4 disease (for 176 patients, EFS and OS 81% ± 3% and 93% ± 2%, respectively) was inferior to that of patients with INSS stage 3 or 4S but did reach the overall study goal of maintaining a 3-year OS greater than 90% for all patients. Ploidy was significantly associated with outcome for patients of all ages. This study was followed in the COG by a study that prospectively used 1p and 11q status to further stratify patients and reduce therapy for patients whose tumors lack LOH at 1p and 11q and who have other favorable biologic factors.[261] The results of this study are still pending, but early reports suggest that excellent OS can be maintained despite the reduction of therapy in intermediate-risk patients who have favorable risk factors.

Existing data suggest that adjuvant therapy could be further reduced despite the presence of gross residual tumor in patients with locoregional tumors who have favorable biology. Traditionally, patients receive chemotherapy with the goal of facilitating surgical resection.

Experience from Memorial Sloan Kettering Cancer Center showed that patients with non–stage 4, non–*MYCN*-amplified disease who had gross residual disease after initial surgery could be safely observed and could maintain an excellent survival rate without use of cytotoxic therapy.[418] In this report only 1 of 22 patients required chemotherapy, and 4 of 13 patients with gross residual disease required a second surgery. This outcome is also supported by the European experience. In the German neuroblastoma 97 protocol, infants who had stage 2 or 3 MYCN nonamplified tumors with incomplete resections were observed postoperatively without use of adjuvant chemotherapy. Regression without further treatment was seen in 32 of 55 patients, and salvage therapy was effective for patients who progressed or experienced a recurrence, with a 3-year OS rate of 98%.[405] On the basis of this information, the most recent COG intermediate-risk study used partial response as the treatment end point in patients with favorable biology and INSS stage 2 or 3 disease.

Treatment of High-Risk Disease

Treatment of disseminated neuroblastoma remains one of the greatest challenges in pediatric oncology. High-risk neuroblastoma represents more than half of all newly diagnosed neuroblastoma cases and is the cause of most of the mortality associated with the disease. Treatment approaches that utilize a combination of intensive induction therapy, myeloablative consolidation therapy with stem cell support, and biologic therapy for minimal residual disease have improved 5-year survival rates from less than 15% to 30% to 40%.[259,419] This modest improvement in survival, however, has come at the cost of increased doses of both chemotherapy and radiotherapy, significantly increasing treatment-related morbidity in disease survivors.

Induction Therapy

The goal of induction therapy is to maximally reduce the overall tumor burden by using a combination of chemotherapy, surgery, and radiation therapy. High-risk neuroblastoma is generally sensitive to initial chemotherapy, even in cases with MYCN amplification. A retrospective meta-analysis of 44 trials showed that a correlation existed between dose intensity and treatment efficacy, including improved response and survival.[420] Induction chemotherapy for high-risk neuroblastoma generally consists of five to seven alkylator and platinum-based cycles using agents selected to reduce cross-resistance. A number of combinations have been used in the United States and Europe, including a regimen developed at Memorial Sloan-Kettering Cancer Center that has been widely used. This regimen consists of cycles of cyclophosphamide, vincristine, and doxorubicin alternating with cycles of cisplatin and etoposide. In a single-institution study of this regimen, Kushner et al.[421] reported a complete response rate of 63% and a complete plus very good partial response rate of 87% in 24 patients. The French Society of Pediatric Oncology Neuroblastoma Study Group used this induction regimen in a multiinstitution study of 47 patients and found a complete response rate of only 45%.[422] Similar results were obtained in the COG A3973 phase III trial, where 242 of 477 patients (51%) attained a complete or very good partial response, suggesting that chemotherapy resistance during induction remains an obstacle to cure.[423]

One strategy to improve induction response is to decrease treatment intervals during induction to lead to more rapid cell death with less chance of drug resistance. Pearson and colleagues[424] (2008) reported a European randomized clinical trial comparing treatment of 262 patients with stage 4 neuroblastoma using rapid-timing chemotherapy (i.e., a cycle every 10 days) versus standard-timing chemotherapy (i.e., a cycle every 21 days) using the same cumulative doses of five chemotherapeutic drugs given over 10 weeks or 18 weeks. The rapid regimen, also known as COJEC (cisplatin, vincristine, carboplatin, etoposide, and cyclophosphamide) was feasible without markedly increased toxicity. Complete or very good partial responses were achieved in 53% of patients assigned to conventional treatment and in 71% of patients assigned to rapid treatment ($P = 0.002$), although no significant difference in OS was found between the two regimens.

The COG piloted an alternative strategy of using non–cross-resistant chemotherapeutic agents to further improve induction response rates. Topotecan is a topoisomerase-1 inhibitor that has shown antineuroblastoma activity in both phase I and II trials with a limited toxicity profile, including dose-limiting myelosuppression and mild to moderate nausea, vomiting, and mucositis.[425,426] Thirty-one patients were enrolled in a COG feasibility trial that incorporated high-dose topotecan into the Memorial Sloan-Kettering backbone.[427] The induction regimen was well tolerated, without unexpected toxicities. Fifteen of 31 patients (48%) achieved a complete or very good partial response. This regimen was recently studied by the COG in a large phase III trial in a large patient population to more accurately access efficacy; the results are pending.

A growing body of evidence suggests that the quality of induction response correlates with outcome. Ladenstein and colleagues[428] performed a multivariate analysis of 549 patients with high-risk neuroblastoma included in the European Bone Marrow Transplantation Solid Tumor Registry and showed that persistent cortical bone lesions ($P = .004$) and bone marrow involvement ($P = .03$) were the only independent adverse prognostic factors. This report included patients treated over a 14-year period, leading to significant interpatient treatment variability. More recent smaller retrospective studies have shown that MIBG response at the end of induction assessed by semiquantitative scoring methods directly correlates with EFS after myeloablative therapy.[429-431] Yanik and colleagues[432] assessed a semiquantitative MIBG score using the Curie scoring system for patients with INSS stage 4 disease who were treated in the COG A3973 trial at diagnosis ($n = 280$) and at the end of induction ($n = 237$). They found that patients who had a Curie score greater than 2 at the end of induction ($n = 52$) had a significantly decreased EFS compared with patients who had Curie scores of 2 or less (3-year EFS 15.4% ± 5.3%

vs. 44.9% ± 3.9%, $P < .001$). Patients who had MYCN amplification with a Curie score greater than 2 ($n = 6$) at the end of induction were particularly affected, with a 3-year EFS of 0% compared with 44.2% ± 6.9% for patients with MYCN amplification who had a Curie score of 2 or less ($n = 65$). These results support previous studies that showed that residual disease at the end of induction measured using Curie scoring of MIBG scans is clearly associated with a worse outcome in patients with high-risk disease. Efforts to further improve survival may need to include response-based end-of-induction treatment stratification, and alternative treatment strategies should be strongly considered for patients with Curie scores greater than 2.

Local Control

Patients with high-risk disease usually have large and locally invasive primary tumors that chemotherapy alone is unlikely to eradicate. Local control is obtained using a combination of surgery and local radiation therapy. Definitive surgery on the primary tumor is usually performed near the end of induction therapy after four to five cycles of chemotherapy. Delaying surgical resection until after chemotherapy has been shown to improve resectability and may reduce the surgical complication rate.[433,434] However, the benefit of complete resection in the treatment of high-risk neuroblastoma remains controversial because the impact of aggressive treatment of the primary tumor site on EFS is unclear in the face of metastatic disease. Several retrospective studies have shown contradictory results. La Quaglia and colleagues[435] reviewed 141 patients treated at Memorial Sloan-Kettering Cancer Center with sequential protocols between 1979 and 2002 and showed evidence of a significant improvement in survival with a gross total resection. Similarly, Adkins and colleagues[433] reviewed the 210 patients (out of 539 total patients) entered in the CCG 3891 study who achieved a complete response by resection and showed a trend toward improved 5-year EFS and OS. However, a report from St. Jude Children's Research Hospital that examined the extent of resection compared with outcome in 107 children older than 1 year with stage 4 neuroblastoma treated with one of four consecutive protocols between 1984 and 2001 showed no evidence of association between survival and the extent of surgery.[436] In addition, Von Allmen and colleagues[437] reported on the local control of 76 patients treated at two institutions using the same treatment protocol with a consistent surgical approach. They found that aggressive surgery followed by local radiation provided excellent local tumor control with no isolated local occurrences in patients who had greater than 90% resection (60 of 76 patients). However the completeness of resection was not correlated with a difference in EFS or OS. Further prospective evaluation of the role of surgery in high-risk neuroblastoma is needed. It is likely that resectability is a surrogate for tumor biology. Gross total resection with nodal resection should be the goal to provide adequate local control, but it should not be performed if it is done at the cost of vital organs or significant postoperative morbidity that would lead to a delay in further therapy.

Neuroblastoma is a highly radiosensitive tumor, and local radiation directed at the primary tumor site in persons with high-risk disease has been shown to decrease the risk of local recurrence.[377,438,439] The total dose generally used in the United States is 2160 cGy in daily 180-cGy fractions to the postinduction chemotherapy, preoperative primary tumor volume. Local radiation is generally used either at the end of induction or after recovery from consolidation chemotherapy. Patients whose radiation field includes their liver may be at higher risk of veno-occlusive disease if radiation is used prior to stem cell transplant.[440] To reduce the possibility of local recurrence after an incomplete surgical resection, the most recent COG study investigated giving patients who have an incomplete resection of the primary tumor an additional boost of 1440 cGy to the gross residual volume in addition to the standard 2160 cGy (for a total dose of 3600 cGy to the gross residual tumor volume). Results of this intervention are still under analysis.

Proton therapy, which can result in improved sparing of normal tissue, is becoming more widely available for pediatric patients. Preliminary studies show no difference in local control compared with photons.[441,442] Assessment in regard to improvement in late toxicity will require long-term follow-up of a large group of patients.

Consolidation Therapy

The goal of the consolidation phase of therapy for patients with high-risk neuroblastoma is to consolidate the response obtained during induction by eliminating any remaining tumor cells using myeloablative chemotherapy and stem cell rescue. The role of dose intensification to overcome tumor drug resistance mechanisms followed by bone marrow or peripheral blood stem cell support has been investigated for more than 20 years. Early nonrandomized studies suggested a survival advantage compared with historic control subjects but may have been influenced by selection bias.

The CCG conducted a randomized study from 1991 to 1996 to test the hypothesis that consolidation with myeloablative chemotherapy followed by purged autologous bone marrow rescue would improve EFS probability compared with nonmyeloablative consolidation chemotherapy.[443] A total of 539 eligible patients were enrolled in this clinical trial, and 379 patients were randomly assigned to myeloablative therapy (consisting of carboplatin, etoposide, melphalan, and 1000 cGy of total body irradiation) with autologous marrow rescue ($n = 189$) or continuation chemotherapy ($n = 190$). An intent-to-treat analysis showed a significant improvement in 3-year EFS for the patients assigned to myeloablative therapy (34% ± 4% vs. 22% ± 4%; $P = 0.03$; Fig. 54-8, *A*). A follow-up report of this study assessing long-term outcomes confirmed the benefit of myeloablative therapy, with a 5-year EFS of 30% ± 4% for patients treated with myeloablative chemotherapy versus 19% ± 3% for patients treated with conventional chemotherapy.[444] The German Society of Pediatric Oncology showed similar results in a randomized study of 295 patients receiving either myeloablative therapy with autologous stem cell rescue ($n = 149$) or consolidation with oral maintenance chemotherapy

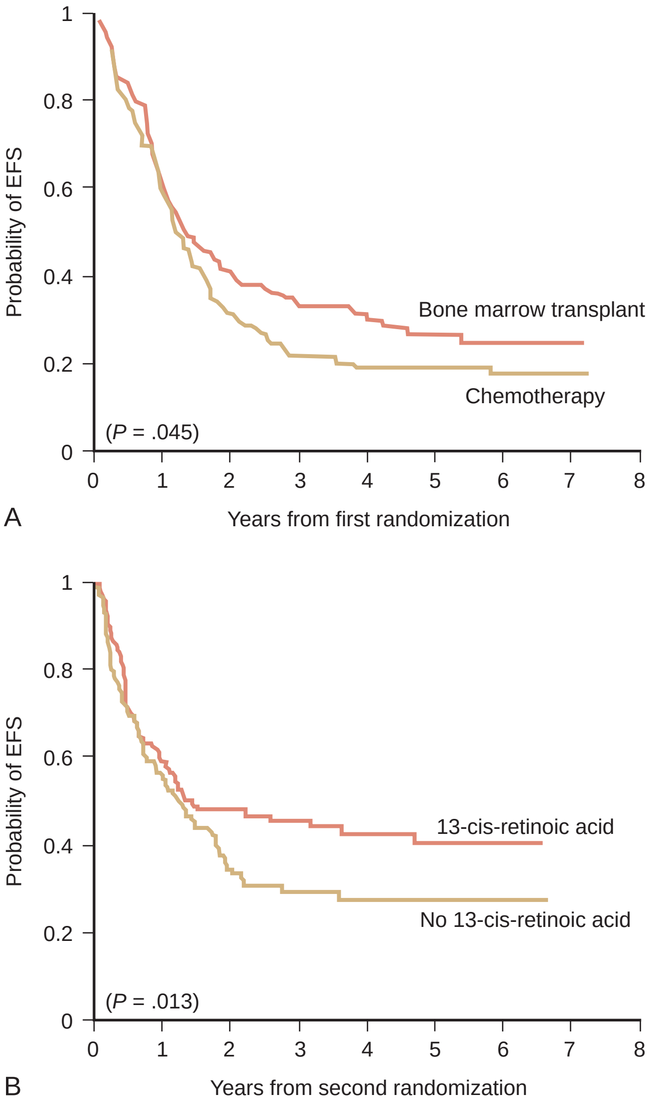

Figure 54-8 Children's Cancer Group study 3891 showing that autologous bone marrow transplant (ABMT) and 13-cis-retinoic acid improve event-free survival for patients with high-risk neuroblastoma. Patients were treated with identical induction chemotherapy, then randomized to ABMT or continuation chemotherapy and then further randomized to receive 13-cis-retinoic acid or no further therapy. **A**, Event-free survival *(EFS)* from time of randomization for patients randomized to ABMT (*n* = 189) or continuation chemotherapy (*n* = 180; *P* = .03). **B**, EFS from time of randomization to 13-cis-retinoic acid (*n* = 130) or no further therapy (*n* = 128; *P* = .03). *(Modified from Matthay KK, Villablanca JG, Seeger RC, et al: Treatment of high-risk neuroblastoma with intensive chemotherapy, radiotherapy, autologous bone marrow transplantation, and 13-cis-retinoic acid. Children's Cancer Group.* N Engl J Med *341:1165–1173, 1999.)*

(*n* = 146). An intent to treat analysis again showed an improvement in 3-year EFS for patients assigned to myeloablative therapy (47%, 95% confidence interval [CI] 38-55, vs. 31%, 95% CI 23-39).[445]

Early myeloablative regimens for high-risk neuroblastoma used bone marrow as rescue with allogeneic marrow showing no survival advantage compared with autologous marrow.[446,447] The use of peripheral blood stem cells results in more rapid engraftment and less transplant-related morbidity.[448,449] In addition, peripheral blood stem cells may be less likely to contain contaminating tumor cells.[450] Peripheral blood stem cells are now the standard for myeloablative autotransplant regimens and are typically harvested after two to four cycles of induction chemotherapy.

An important concern relating to autotransplant is potential tumor cell contamination of the stem cell product contributing to relapse. Strategies to purge tumor cells from harvested marrow or peripheral blood stem cells include ex vivo immunomagnetic purging based on neural-specific antigens or CD34+ selection of hematopoietic progenitor cells.[449,451] A randomized clinical trial designed to test the efficacy of ex vivo purging of immunocytochemically negative peripheral blood stem cell products was performed by the COG. No difference in survival was seen in patients who received immunomagnetic purged stem cells compared with patients who did not receive these stem cells (5-year EFS 40% vs. 36% and 5-year OS 50% vs. 51%).[423]

Given the improvement in EFS observed with single transplant myeloablative strategies, tandem and even triple transplant regimens have been evaluated in limited institution and cooperative group pilot studies. The theoretic advantages to multiple transplants include exposure to multiple non–cross-resistant therapies at maximal doses in a relatively rapid sequence and possible modulation of the tumor microenvironment during the first transplant, potentiating cell killing with subsequent transplant(s).[449] Grupp and colleagues[449] and George and colleagues[452] treated 97 patients with high-risk neuroblastoma between 1994 and 2002 with a tandem rapid sequence myeloablative consolidation regimens using peripheral blood stem cell support in a limited institution single-arm study. They showed that tandem transplant was feasible with rapid myeloid cell recovery and low treatment-related mortality (five treatment-related deaths; 82 patients completed two transplants). The progression-free survival (PFS) rate at 5 years from diagnosis was 47% (95% CI, 36% to 56%), and the PFS at 7 years was 45% (95% CI, 24% to 55%) and the overall survival rate at 5 and 7 years, respectively, was 60% (95% CI, 42% to 64%) and 53% (95% CI, 40% to 64%; Fig. 54-9). This study and several others[453-455] suggest that further intensification of consolidation therapy may affect survival of patients with high-risk neuroblastoma. The COG recently completed a large randomized trial of single versus tandem myeloablative consolidations to further evaluate the true impact of a tandem high-dose myeloablative consolidation strategy, the results of which are still pending.

Using different chemotherapy for myeloablation is an alternative strategy that is being explored for high-risk consolidation therapy. A recent European high-risk neuroblastoma trial randomly compared two myeloablative regimens—busulfan and melphalan versus carboplatin, etoposide, and melphalan. Randomization was stopped early because of an interim analysis that showed that the regimen containing busulfan had a superior outcome (a 3-year EFS of 49% vs. 33% and a 3-year OS of 60% vs. 48%).[456] In this study the rapid COJEC induction regimen

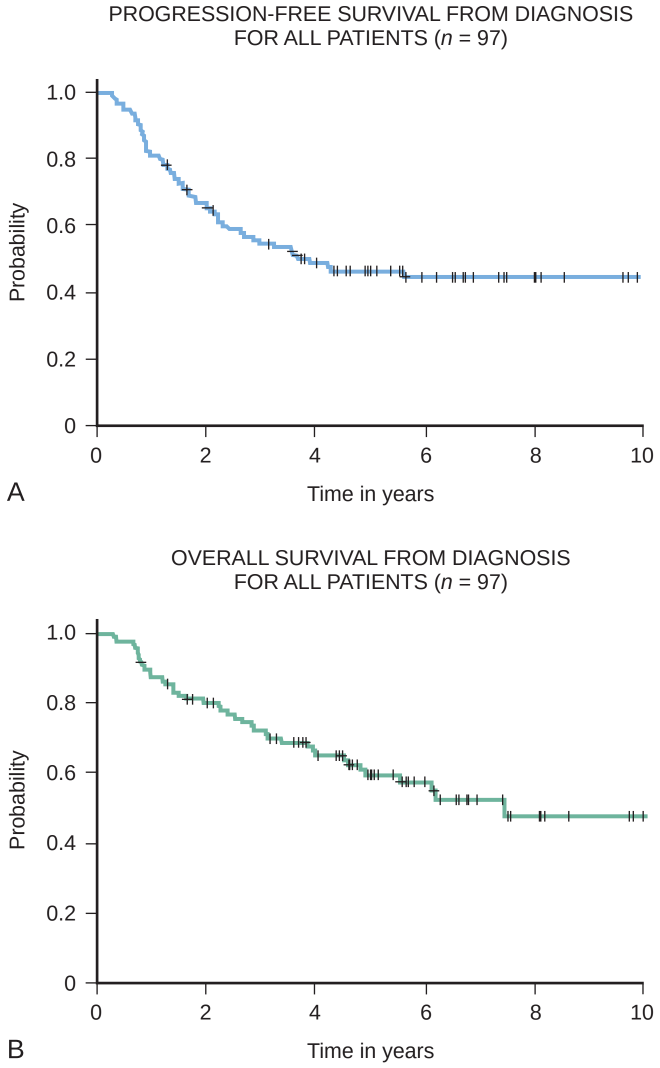

Figure 54-9 Tandem transplant for high-risk neuroblastoma. Progression-free survival (**A**) and overall survival (**B**) from diagnosis of 97 patients. *(From George RE, Li S, Medeiros-Nancarrow C, et al: High-risk neuroblastoma treated with tandem autologous peripheral-blood stem cell-supported transplantation: long-term survival update.* J Clin Oncol *24:2891–2896, 2006.)*

was used for all patients.[457] The high cumulative dose of platinum in this regimen may help explain the lower-than-expected survival for the arm containing carboplatinum, etoposide, and melphalan. Although results are still being analyzed, conditioning with busulfan and melphalan had less associated acute toxicity. The COG is running a pilot study to determine the feasibility of using busulfan and melphalan as consolidation therapy after the COG induction used in the last randomized trial. If feasible, this regimen will likely be used in the next COG phase III high-risk study.

Treatment of Minimal Residual Disease

Even when a complete remission is obtained after myeloablative therapy and stem cell rescue, relapse remains a significant problem, suggesting the presence of highly chemotherapy-resistant minimal residual disease. Alternative strategies targeting unique biologic features of neuroblastoma have therefore become an important part of current high-risk neuroblastoma treatment strategies after consolidation therapy. Minimal residual disease therapy with 13-cis-retinoic acid has been a standard in high-risk neuroblastoma care since the late 1990s. Immunotherapy targeted against the GD2+ antigen is now being more widely adopted as standard therapy.

The retinoids have been shown to decrease proliferation, decrease expression of the MYCN oncogene, and induce differentiation in neuroblastoma cell lines, including those established from refractory tumors.[458,459] A phase I study of children with high-risk neuroblastoma showed that an intermittent schedule of high-dose 13-cis-retinoic acid after transplant had minimal toxicity (primarily cheilitis, dry skin, and hypertriglyceridemia) and resulted in the clearing of tumor cells in the bone marrow by morphologic assessment in 3 out of 10 patients.[460] The efficacy of 13-cis-retinoic acid was tested in the previously mentioned CCG randomized trial using a factorial design after randomization to myeloablative or continuation chemotherapy.[443] A total of 130 patients were randomly assigned to receive either six cycles of 13-cis-retinoic acid or no further therapy. The cohort of patients assigned to receive posttransplant therapy with 13-cis-retinoic acid had a significantly improved EFS probability (46% ± 6% vs. 29% ± 6% from second randomization; $P = .03$; see Fig. 54-8, *B*). Ongoing studies of 13-cis-retinoic acid are focusing on the pharmacokinetics and proper dosing of 13-cis-retinoic acid, particularly in the youngest patients, as well as potential late toxicities of chronic dosing.[461,462]

Another biologic strategy that has been evaluated in the minimal residual disease phase of therapy is antibody therapy directed against the GD2 disialoganglioside that is uniformly expressed on neuroblastoma cells. Murine, chimeric, and humanized antibodies have shown activity in preclinical models, particularly in the minimal residual disease setting,[463-465] as well as phase I and II clinical trials.[377,466-468] The COG completed a randomized clinical trial testing the efficacy of ch14.18 with IL-2 and granulocyte-macrophage colony-stimulating factor and 13-cis-retinoic acid versus 13-cis-retinoic acid alone after myeloablative chemotherapy. The results showed a significant improvement in 2-year EFS and OS in the immunotherapy group compared with the patients who received isotretinoin alone (EFS, 66% ± 5% vs. 46% ± 5%, and OS, 86% ± 4% vs. 75% ± 5%[469]; Fig. 54-10). A nonrandomized trial of ch14.18 given alone that was performed by Simon and colleagues[470] showed no benefit of antibody therapy, suggesting that cytokine-mediated activation of antibody-dependent cell-mediated toxicity may be necessary. GD2 has restricted distribution in normal tissue to neurons, skin melanocytes, and peripheral sensory nerve fibers, and thus the toxicities usually associated with chemotherapy are not seen with immunotherapy. Instead, neuropathic pain can be a significant adverse effect in addition to cytokine-mediated capillary leak and hypersensitivity reactions associated with either the antibody or cytokines. Ongoing studies are exploring alternative antibodies, as well as alternative methods of cytokine delivery, as discussed later.

Assessment of Response to Treatment

For neuroblastoma, response to treatment is assessed using the International Neuroblastoma Response criteria, which are detailed in Table 54-8.[371] Determination of overall response requires assessment of both primary and metastatic sites. This assessment should be made using the same modalities that were used at diagnosis. The timing of response assessments varies according to protocol and risk group, but they are generally performed at the end of induction, before and after surgical procedures, and at the end of treatment. In addition to these response criteria, semiquantitative scoring systems for evaluating MIBG-positive disease have been developed.[429,471] As previously mentioned, the Curie scoring system has prognostic significance in patients with high-risk neuroblastoma. The ability to objectively quantify MIBG response is also useful in clinical trials for relapsed disease. Patients who have had a relapse often have only bone and/or bone marrow disease that can be seen with a MIBG scan but cannot be measured by CT or MRI using standard response criteria.

Late Effects of Therapy

Improvements in survival of patients with high-risk neuroblastoma during the past 20 years has come at the cost of intensification of therapy, putting these patients at increased risk of experiencing late effects of treatment. Hearing loss caused by exposure to high cumulative doses

TABLE 54-8 Definitions of Response to Treatment[371,381]

Response	Primary*	Metastases*	Markers*
1. CR	No tumor	No tumor (chest, abdomen, liver, bone, HVA/VMA bone marrow, nodes, etc.)	HVA/VMA normal
2. VGPR	Reduction >90% but <100%	No tumor (as above except bone); no new bone lesions, all preexisting lesions improved	HVA/VMA decreased >90%
3. PR	Reduction 50%-90%	No new lesions; 50-90% reduction in measurable sites; 0-1 bone marrow samples with tumor; bone lesions same as VGPR	HVA/VMA decreased 50%-90%
4. MR	No new lesions; >50% reduction of any measurable lesion (primary or metastases) with <50% reduction in any other; <25% increase in any existing lesion†		
5. NR	No new lesions; <50% reduction but <25% increase in any existing lesion†		
6. PD	Any new lesion; increase of any measurable lesion by >25%; previous negative marrow positive for tumor		

CR, Complete response; *HVA,* homovanillic acid; *MR,* mixed response; *NR,* no response; *PD,* progressive disease; *PR,* partial response; *VGPR,* very good partial response; *VMA,* vanillylmandelic acid.

*Evaluations of primary and metastatic disease as outlined in the text.

†Quantitative assessment does not apply to marrow disease.

of platinum chemotherapy at a young age is a particular problem that can put survivors at risk for learning problems and psychosocial difficulties.[472] Use of high doses of alkylating agents and topoisomerase inhibitors often results in sterility and puts patients at an increased risk of secondary leukemias.[473,474] Neuroblastoma survivors who received total body irradiation are also at risk for growth delay, cataracts, and thyroid insufficiency, as well as the risk of secondary cancers.[475] Survivors of high-risk neuroblastoma therapy should be followed-up regularly throughout their lifetimes with anticipatory management for these potential problems.[476]

NOVEL THERAPIES

Despite the intensive multimodal treatment that was previously described, more than half of children with high-risk neuroblastoma have a 5-year EFS of less than 50%.[343] Currently no standard treatment regimen exists for patients with relapsed neuroblastoma. Cytotoxic chemotherapy regimens for relapsed neuroblastoma are typically based on the camptothecin derivatives topotecan and irinotecan. Topotecan has been combined with both cyclophosphamide and with vincristine and doxorubicin in phase II studies.[477,478] Irinotecan is most commonly given with temozolamide[479] and is being used more frequently in the United States now that topotecan is being used in induction therapy for high-risk patients in the COG. Neither topotecan nor irinotecan-based therapies led to ultimate cure. Using novel strategies that are targeted to tumor-specific genetic alterations up front in conjunction with standard chemotherapeutic agents may improve cure rates without increased toxicity. Several of these targeted therapies are in clinical or preclinical development, as described later.

Targeted Radiotherapy

In addition to its use for staging and response evaluations, MIBG can be labeled with ^{131}I and used to deliver targeted radiotherapy. ^{131}I-MIBG has undergone extensive single-institution and, more recently, cooperative group clinical trials for the treatment of refractory neuroblastoma.[416,32] The results from a phase II study of 164 patients show that MIBG is active against refractory neuroblastoma with an objective response rate of 36% and disease stabilization in 34% of patients with frequent palliation of pain.[480] Treatment-related toxicity, even at substantial doses, is usually minimal. The most significant reported toxicity is hematologic with prolonged thrombocytopenia, which is most marked in patients with tumor in the bone marrow, and myelosuppression, both of which can be abrogated by autologous stem cell infusion.[480,481] Nonhematologic toxicities include brief nausea and vomiting, transient hepatic dysfunction, and chemical hypothyroidism. More recent clinical trials have focused on combining MIBG with potential radiosensitizing agents with known activity in neuroblastoma to enhance efficacy. The New Approaches to Neuroblastoma Therapy (NANT) consortium completed two phase I studies combining MIBG with a radiosensitizer. In the first study, MIBG was combined with irinotecan and vincristine, and it was shown that MIBG could safely be given at the single-agent maximal tolerated dose along with standard doses of chemotherapy.[482] In the other study, MIBG was combined with vorinostat, a histone deacetylase inhibitor that has been shown to increase the expression of functional norepinephrine transporters in neuroblastoma preclinical models and has completed accrual.[483] The NANT consortium next plans on performing a three-way phase II comparison of both combinations and MIBG as a single agent. In addition to MIBG, radiolabeled anti-GD2 antibodies are also under investigation to provide targeted radiotherapy.[484]

A phase I dose escalation study of ^{131}I-MIBG followed by myeloablative carboplatin, etoposide, and melphalan with stem cell rescue showed a response rate of 27% in patients who were refractory to standard therapy. Based on these promising results in patients who were refractory to treatment, a phase II study at the maximal tolerated dose was completed.[485,486] The COG is currently performing a pilot study to determine the feasibility of giving ^{131}I-MIBG prior to consolidation therapy in newly diagnosed high-risk patients.

Immunotherapy

As previously discussed, a monoclonal antibody directed against the GD2 antigen in combination with cytokines has been shown to significantly improve survival and is now being used as a standard part of the minimal residual disease phase of treatment in newly diagnosed high-risk patients. Current research is focusing on enhancing efficacy and making the regimen less toxic. To this end, the chimeric anti-GD2 antibody is being piloted with subcutaneous (rather than intravenous) IL-2[487] and with lenolidomide, which has been shown to enhance NK cell–mediated antibody dependent cellular cytotoxicity in preclinical models.[465,488] Humanized antibodies are also being developed that are designed to cause less hypersensitivity-type reactions and have increased tumor specificity. One of these antibodies, hu14.18K332A, has a single amino acid mutation that limits its ability to fix complement and thereby reduced the pain associated with ch14.18 while retaining the antibody-dependent cellular toxicity capabilities.[488a] Additionally, preclinical studies have shown that antibody efficacy can be enhanced by creating a fusion protein consisting of antibody linked to a cytokine such as IL-2.[463] A phase II study of a humanized GD2 antibody fused to IL-2 (hu14.18-IL2) showed a complete response in 5 of 24 patients with MIBG and/or bone marrow disease with tolerable toxicity, warranting further investigation.[489]

One limitation of monoclonal antibody therapy in patients with neuroblastoma is that it seems to be most active in the setting of minimal residual disease, with questionable benefit in patients who have bulky disease. More active immunotherapy strategies are also being developed to try to address this problem. These strategies include use of immunostimulatory antibodies such as ipilimumab (anti-cytotoxic T-lymphocyte antigen 4) and vaccination with anti-idiotype antibody or dendritic cells.[490-492] In addition, engineered cytolytic T lymphocytes that are directed against tumor-associated antigens (chimeric antigen receptor T cells) are under development with encouraging preliminary results.[493,494]

Molecular Targeting

Several large-scale sequencing efforts have concluded that sequence alterations are not represented in neuroblastoma in a major way, especially those that can be readily targeted therapeutically. However strategies focused on targeting genetic pathways relevant to proliferation of neuroblastoma cells hold promise. Additionally, alterations in chromatin remodeling and other epigenetic regulators may provide novel avenues for therapeutic intervention.

ALK

ALK mutations have been established as oncogenic drivers in neuroblastoma and offer bona fide therapeutic targets.[495] ALK small molecule inhibitors may be beneficial not only to 10% to 12% of patients with neuroblastoma who have mutation and amplification, but also to the proportion whose tumors overexpress the wild-type, phosphorylated ALK receptor and that appear to respond to genetic and chemical ALK depletion by undergoing apoptosis (Fig. 54-11).[186,198]

Small Molecule Inhibitors. The first ALK inhibitor to be developed was NVP-TAE684 (Novartis), a 5-chloro-2, 4-diaminophenylpyrimidine compound that induces significant cytotoxicity in neuroblastoma cells expressing different ALK mutations (Fig. 54-12).[155,496,497] This highly selective ATP-competitive inhibitor was identified by screening a kinase-targeted small molecule library against Ba/F3 cells expressing oncogenic kinases, specifically NPM-ALK.[496] TAE684 is especially selective for ALK because the orthomethoxy group of TAE684 projects into a small groove located between the side chains of residues L258 and M259 of the NPM-ALK kinase domain; bulkier amino acids at the L258 position (which are seen in other kinases) would lead to a steric clash with TAE684.[496] Treatment of neuroblastoma cells harboring the F1174L and the R1275Q ALK mutations induces rapid inhibition of phosphorylated ALK and its downstream signaling, leading to apoptosis and cell cycle arrest.[155,497] However TAE684 could not be taken forward to clinical development because it tends to form an extensive number of reactive adducts upon metabolic oxidation, which creates the potential for significant toxicity.[498] Nevertheless, it remains a valuable compound for preclinical studies of ALK kinase inhibition.

Crizotinib (PF-2341066; Xalkori), an orally bioavailable, 2,4-pyrimidinediamine derivative, is an ATP-competitive dual inhibitor of MET and ALK.[499,500] Crizotinib binds to the inactive conformation of both MET and ALK[501] and has shown striking efficiency against ALK-rearranged tumors, both in mouse models

and in the clinic.[500,502] In early-phase clinical testing, for example, at a mean treatment duration of 6.4 months, the overall response rate was 57% in patients with EML4-ALK–positive NSCLC.[502] Crizotinib has also shown striking responses in adult patients with other ALK-rearranged cancers such as inflammatory myofibroblastic tumor (IMT) and anaplastic large-cell lymphoma (ALCL).[503,504] A phase III trial showed a superior PFS and overall response rate for crizotinib compared with chemotherapy in patients with NSCLC who had disease progression after standard chemotherapy.[505] Because of this result, crizotinib was granted approval for the treatment of patients with ALK-positive metastatic NSCLC by the U.S. Food and Drug Administration (FDA).

Unfortunately, the same positive results have not been observed in patients with neuroblastoma. When tested against neuroblastoma cells bearing either of two of the more common mutations, crizotinib inhibited growth and induced apoptosis in cells expressing ALK^{R1275Q} but failed to inhibit the growth of ALK^{F1174L}-positive cells.[194,506] The relative resistance of ALK^{F1174L} to crizotinib has been attributed to either lack of direct contact with the crizotinib-binding site within the ATP-binding pocket or the increased ATP-binding affinity of the mutant, with complete inhibition of constitutively active ALK attainable only at very high doses of the drug.[191] Crizotinib was tested in a COG phase I trial that included patients whose tumors expressed aberrant ALK. With results similar to those in adult patients and as expected from preclinical studies, patients whose tumors expressed translocated ALK (ALCL and IMT) responded very well to the drug.[507] However, the results for patients with neuroblastoma whose tumors harbored point mutations within the full-length receptor were less encouraging, with only 1 of 11 patients with ALK-mutated neuroblastoma showing an objective response to this agent.[507] Moreover, ALK mutations exhibit differential sensitivity to crizotinib. In this study, three of the four patients with ALK^{F1174L}-positive neuroblastoma tumors experienced progressive disease, compared with two of five whose tumors had a missense mutation at the R^{1275} locus.[507] Therefore crizotinib as a single agent does not appear to be sufficient to induce tumor regression in neuroblastoma. Other studies have shown that the cytotoxicity of crizotinib could be significantly enhanced by targeting the critical downstream pathways that mediate ALK signaling.[194,508,509] The ALK^{F1174L} mutation signals through the PI3K/mTOR pathway,[156] and combined inhibition of ALK and mTOR induces tumor regression and prolongs the survival of mice both in xenografts and transgenic models of neuroblastoma.[194,509] Therefore clinical trials of crizotinib in combination with downstream pathway inhibitors may enhance the antitumor activity of the former, and in particular, their ability to overcome the resistance of ALK^{F1174L}-mutated neuroblastoma cells to crizotinib.

Several other compounds are in development or are even in early-phase trials in adults with ALK-aberrant cancers.[498,510] LDK378 (Novartis Pharmaceuticals, Basel, Switzerland), which is derived from TAE684,[496] is an orally active inhibitor of the ALK kinase. In cellular assays, LDK378 inhibits ALK at an inhibitory concentration of 50% of 40 nM against wild-type ALK and of 22 nM against NPM-ALK. It also has an excellent pharmacokinetic profile in rodents, with an oral bioavailability of greater than 50%. LDK was shown was shown to induce a response rate of 80% in patients with NSCLC who had experienced disease progression after an initial response to crizotinib, and therefore this drug has received "breakthrough therapy" designation from the U.S. FDA for patients with ALCL or metastatic NSCLC whose disease progressed while being treated with crizotinib or who are intolerant to it. LDK is currently in phase II trials for NSCLC. It is currently being tested in phase I trials in pediatric patients (NCT01283516, ClinicalTrials.gov), and it may hold promise for the treatment of patients with neuroblastoma who have mutated ALK.

Other ALK inhibitors in development include CH5424802 (Roche/Chugai Pharmaceuticals, Ltd., Tokyo, Japan),[510] an orally available inhibitor that was shown to potently inhibit the growth of neuroblastoma cells expressing amplified ALK. This agent also displayed in vitro inhibitory activity against neuroblastoma cells expressing $\text{ALK}^{\text{F1174L}}$, which was shown to be comparable to that achieved in cells with wild-type ALK.[510] Whether CH5424802 will show efficacy for in vivo models of neuroblastoma with mutated ALK remains to be seen. Other ALK inhibitors in phase I/II clinical trials include ASP3026 (Astellas Pharma, Northbrook, Ill.),[511] CEP-28122 (Cephalon Inc., Frazer, Pa.),[512] AP26113 (ARIAD, Cambridge, Mass.), a small molecule that has exhibited activity as a potent dual inhibitor of ALK and epidermal growth factor receptor,[513] and X-396 (Xcovery, West Palm Beach, Fla.).[514]

ALK-Based Immune Therapy. The abundant expression of ALK on the surface of most neuroblastoma tumor cells and its restricted tissue expression in normal tissues render it an ideal tumor-associated antigen.[199] Treatment of neuroblastoma cell lines with ALK-specific monoclonal antibodies has been shown to induce enhanced immune cell-mediated cytotoxicity with inhibition of cell proliferation and cell death.[515] Moreover exposure to crizotinib induced accumulation of ALK on the cell surface, thus increasing the accessibility of the antigen for antibody binding. If validated in vivo, this strategy may be useful in cases of neuroblastoma that constitutively express ALK, either alone or in combination with small-molecule inhibitors. Other avenues such as treatments with an ALK-based chimeric antigen receptor are being actively explored.

RNA Interference-Based Therapeutic Strategies. Nanoparticles carrying ALK small interfering RNA have been shown to be effective in inducing antitumor activity in ALK-expressing neuroblastoma models.[516] In this study, the use of a special anti-GD2 targeted liposomal formulation of nanoparticles ensured the death, as well as specific and nontoxic delivery, of ALK-small interfering RNA GD2 expressing neuroblastoma cells. Although still far removed from the clinic, these preliminary results have the potential to be developed into therapies for children with neuroblastoma.

Resistance to ALK Inhibitors. One issue with molecularly targeted agents is the inevitable development of resistance, as has been observed with crizotinib.[508,517] Even if the small-molecule inhibitor is potent enough to block tumor growth once a tumor has acquired additional aberrations, this strategy generally becomes ineffective, leaving the patient with static disease that begins to progress once treatment is stopped.[518] Resistance to targeted agents usually develops as a result of the development of secondary mutations or activation of compensatory signaling pathways. Secondary mutations are frequently acquired in the "gatekeeper" position, where the presence of amino acids with bulky side chains such as methionine interferes with the binding of the kinase inhibitor. The ALK L1196 mutation has been identified in a patient with lung cancer with an EML4-ALK tumor translocation, after an initial response to crizotinib.[517] The F1174L mutation that occurs de novo in neuroblastoma also developed in a patient with IMT bearing the RAP2-ALK translocation who experienced a relapse after therapy with crizotinib that was initially successful.[191] Another mechanism by which cancer cells with activated mutant kinases evade treatment with kinase inhibitors is to switch to alternative signaling pathways. Thus NSCLC cells with MET gene amplification develop resistance to crizotinib by overexpressing the epidermal growth factor receptor.[519] Preclinical models of resistance will enable prediction of resistance mechanisms to newer ALK inhibitors and aid in the design of drug combinations to delay or even prevent resistance.

Targeting Amplified MYCN

Because deactivation of MYCN in MYCN-expressing neuroblastoma tumors causes proliferative arrest and tumor regression, treatment strategies focused on silencing MYCN would be expected to affect an appreciable proportion of patients with high-risk neuroblastoma. Yet direct targeting of MYCN has proved difficult because (1) it lacks an obvious "druggable" domain, and (2) its requirement in normal cells imposes a high risk of prohibitive nonspecific toxicity. However, it is possible to target MYCN indirectly through the molecules that regulate MYCN activation or stability either at the mRNA or protein level. These strategies include inhibition of epigenetic proteins such as BRD4,[520,521] decreasing MYCN protein stability through inhibition of aurora kinase,[522] or targeting molecules that are synthetic lethal to the growth and proliferative activity of MYCN.[523] Other methods include activation of p53-induced apoptosis,[524] differentiation induction,[141] and inhibiting MYCN-dependent metabolic dependencies.[525,526] A major consideration in thinking about strategies to inhibit MYCN regulation and function is to have a therapeutic window sufficient for antitumor activity without inducing severe toxicity to normal tissues.

BET Bromodomain Inhibitors. The bromodomain and extraterminal (BET) family of transcriptional coactivators are epigenetic reader proteins that recognize and bind to covalent modifications of chromatin[527] to promote gene activation. BET proteins BRD2, BRD3, and BRD4 have been found to be critical in promoting transcription of MYC and MYCN through their recognition of lysine side-chain acetylation on histone tails.[520,528] JQ1 is a novel thienotriazolo-1,4-diazepine compound that displaces BET bromodomains from chromatin by competitively binding to the acetyl lysine recognition pocket.[528] JQ1 suppresses the growth of MYCN-amplified neuroblastoma in both orthotopic models and transgenic *TH-MYCN*-MYCN models, with a significant increase in survival. Tumors showed increased apoptosis and decreased proliferation concomitant with decreased expression of MYCN.[520] JQ1 displaces BRD4 from the MYCN promoter, with depletion of MYCN mRNA and protein after its administration. Downregulation of the MYCN transcriptional program was induced in JQ1-treated cells, with genes involved in proliferation, apoptosis, neural crest stemness, and cellular differentiation being particularly affected. Therefore BET bromodomain inhibition may be a promising option for patients with MYCN-amplified neuroblastoma, and clinical trials are being developed.[520] Similar results were also seen with another BRD4 inhibitor GSK1324726A (I-BET726), which induced potent growth inhibition and cytotoxicity in most neuroblastoma cell lines tested irrespective of MYCN copy number or expression level.[521]

Although MYCN amplification predicted sensitivity to BRD4 inhibition in these two studies, cell lines that were sensitive to JQ1 did not always have MYCN amplification, suggesting that MYC or MYCN is not the sole predictor of sensitivity to BET inhibition. Wyce et al.[521] (2013) reported that BRD4 inhibition led to direct suppression of BCL2 in addition to MYCN, although neither protein fully accounted for the sensitivity of I-BET726 in neuroblastoma cells.

Aurora Kinase Inhibitors. The aurora serine/threonine protein kinase–A is critical for the stabilization of MYCN. Aurora kinase A (AURKA) associates with MYCN and prevents its Fbxw7 ubiquitin ligase-mediated proteosomal degradation.[522,529] AURKA also plays an important role in centrosome maturation and spindle formation during mitosis.[530] AURKA overexpression has been reported in MYCN-amplified neuroblastoma[531]; these cells depend on high levels of this protein for maintaining MYCN function.[522,531] The Aurora-A inhibitors, MLN8054 and MLN8237, have shown promising activity in neuroblastoma models.[529,532,533] These agents disrupt the MYCN-AURKA complex and promote degradation of MYCN. The disruption of the complex inhibits MYCN-dependent transcription, correlating with tumor regression and prolonged survival in a transgenic MYCN neuroblastoma model.[529] Additionally, additive effects have been observed with the combination of MLN8237 and vorinostat, an HDAC inhibitor.[534] AURKA inhibition has also been shown to inhibit angiogenesis in neuroblastoma.[535] MLN 8237 is currently in phase II trials in patients with neuroblastoma (NCT01154816).

PI3K inhibition. Small-molecule inhibitors of PI3K have been shown to block the growth of transgenic neuroblastoma models, and they also induce cell cycle arrest and apoptosis in human neuroblastoma cells with MYCN amplification.[536,523] MYCN is a critical target for PI3K inhibitors.[523] The MYCN protein is stabilized through PI3K signaling,[537] and blockage of PI3K and mTOR can destabilize MYCN, leading to decreased MYCN protein levels and blocked proliferation of tumors driven by TH-MYCN.[536,538] In addition to promoting MYCN degradation, PI3K/mTOR inhibitors have been shown to induce secondary paracrine blockage of angiogenesis. The PI3K inhibitor NVP-BEZ235 improved survival in both human (highly pretreated MYCN-amplified orthotopic xenograft) and transgenic mouse models of MYCN-driven neuroblastoma.[523] Clinical trials of the mTOR inhibitor temsirolimus, in combination with irinotecan and temozolomide, have shown tolerability in patients with relapsed or refractory solid tumors, including neuroblastoma,[539] and phase II trials of the combination are ongoing.

p53-Pathway Inhibition. Another way of inhibiting the effects of MYCN is by targeting the p53-dependent apoptotic pathway activated by MYCN. MDM2, an E3 ubiquitin ligase, mediates p53 degradation, as well as cytoplasmic localization and transcriptional inactivation. Deregulation of the ARF/MDM2 pathway is seen in neuroblastoma tumors, resulting in high MDM2 activity and subsequent p53 deactivation.[540] Uncoupling p53 from MDM2 with small molecules that compete for respective docking sites may offer another avenue for targeted therapy by activating gp53. Nutlin-3, a cis-imidazoline small molecule that mimics a p53-binding peptide, has been shown to interfere with MDM2 binding to p53 and has proven effective in reducing growth and inducing apoptosis in neuroblastoma cells.[541,542] Nutlin-3 has also been shown to prevent tumor metastasis in xenograft models[540] with accumulation of p53 protein, as well as induction of p53 target gene expression. Synergy has been shown between nutlin-3 and DNA-damaging chemotherapeutic agents,[543] as well as with the pan CDK inhibitor roscovitine (Seliciclib)[544] and the anti-VEGF antibody bevacizumab.[545] Nutlin-3 has also been shown to be effective in relapsed neuroblastoma by inhibiting drug efflux activities of P-glycoprotein and multidrug resistance–associated protein 1.[546] Thus nutlin agents may offer benefit in patients with neuroblastoma.

Polyamines. A number of genes involved in polyamine homeostasis are known to be MYCN or c-MYC targets, and the expression of others is linked to *MYCN* status.[525,526] Approaches that target the polyamine pathway may be effective in treating high-risk neuroblastoma, especially those with MYCN amplification. Polyamines are positively charged multifunctional polycations that are critical for cell growth, differentiation, and survival. Polyamine depletion leads to growth arrest, whereas overexpression is cytotoxic; therefore tight regulation of intracellular levels is critical (reviewed in reference 547).[547] Polyamines are elevated in neuroblastoma cells and the gene encoding ornithine decarboxylase–1 (ODC1), the rate-limiting enzyme in polyamine biosynthesis, is a direct transcriptional target of MYCN. ODC1 is coamplified or overexpressed with MYCN and is associated with a poor prognosis in MYCN-amplified tumors.[525] a-difluoromethylornithine (DFMO), which acts as a specific inhibitor of ODC1 and is the most widely studied inhibitor of polyamine metabolism, serves both as a chemotherapeutic and a chemopreventive agent.[548] DFMO treatment in neuroblastoma cell lines inhibited proliferation and increased tumor latency and overall survival in MYCN-driven transgenic neuroblastoma models.[525] It also enhances the effects of the cytotoxic chemotherapeutic agents cyclophosphamide and cisplatin[525] and induces synergistic and antiproliferative effects when combined with the cyclooxygenase 2 inhibitors celecoxib and sulindac.[549] A phase I clinical trial coordinated by the NANT consortium for the treatment of refractory neuroblastoma using high-dose DFMO and celecoxib in combination with standard chemotherapy (cyclophosphamide and topotecan) is under way. Polyamine enhancement is also seen in nonamplified tumors and is associated with high-risk disease, and therefore these strategies may also be effective in the latter group as well.[525,550]

Retinoids

Fenretinide (N-[4-hydroxyphenyl] retinamide; 4-HPR) is a synthetic retinoid that is cytotoxic to neuroblastoma cells in vitro. Unlike 13-cis-retinoic acid, it does not induce tumor differentiation of cells but is cytotoxic by a variety of other mechanisms.[551-553] Its mechanism of action is thought to be through de novo ceramide synthesis induction,[554-556] generation of reactive oxygen species,[557] angiogenesis inhibition,[558,559] and increased NK cell activity.[560] Fenretinide has been tested in preclinical and early phase clinical studies and showed wide interpatient variability of plasma levels with suggested antitumor activity in relapsed disease.[23-26] To improve plasma levels, an oral powder in an organized lipid complex was developed that increased 4-HPR levels in plasma and tissues.[560a] A phase I trial of this formulation of fenretinide confirmed attainment of higher plasma levels with minimal toxicity. Complete tumor responses were observed in patients with tumor involvement limited to bone marrow and/or bone metastasis, suggesting that relapsed patients who commonly present with similar disease may benefit most from this agent.[561]

TRKB Inhibitors

In animal models, CEP-701 (lestaurtinib), a small-molecule inhibitor, has shown activity against the TRKB tyrosine kinase,[562,563] which acts as an oncogenic kinase in a subset of neuroblastomas. In animal models, lestaurtinib alone significantly inhibited tumor growth, and it also enhanced the antitumor efficacy of the cyclophosphamide/topotecan combination.[564] Lestaurtinib was tested in a phase I trial and was found to be well tolerated, with evidence of tolerability of a dose level sufficient to inhibit phospho-TRKB activity in plasma. Additionally, lestaurtinib in combination with 13-cis-retinoic acid was found to be additive or synergistic in neuroblastoma cells.[565]

CDK4/CDK6 Inhibitors

The cyclin D/CDK4/CDK6/RB pathway is hyperactive in many cancers.[566] CDK4 and CDK6 encode serine threonine kinases that complex with D-type cyclins to phosphorylate or inactivate the RB protein. This in turns induces the release of RB from E2F transcription factors, thus allowing progression of G1-S phase progression and cell proliferation. Moreover, CDK4/CDK6 also suppresses senescence through the forkhead box M1 (FOXM1) transcription factor.[566a] Genomic amplification of cyclin D1 and CDK4 has been reported in a subset of neuroblastomas.[567-571] Others have evaluated CDK4/CDK6 inhibitors in neuroblastoma and have shown sensitivity to inhibition, with sensitivity attributed to G1 arrest and cellular senescence. Treatment with the Novartis inhibitor LEE011 reduced proliferation in 12 of 17 lines, although the mean inhibitory concentration of 50% was in the 300-nM range in sensitive lines. It caused cell cycle arrest and cellular senescence that was attributed to dose-dependent decreases in phosphorylated RB and FOXM1, respectively. Treatment resulted in delay of subcutaneous tumor xenografts.[572] Given that CDK4/CDK6 inhibition causes a cytostatic response, it is unclear what the effects would be if it were used in combination with conventional cytotoxic agents that rely on S-phase DNA replication,[573] and further studies may be required to provide elucidation. Therefore CDK4/CDK6 inhibition may be most effective in postchemotherapy maintenance treatment.

HDAC Inhibitors and Demethylating Agents

It is becoming increasingly clear that not only in other cancers but also in neuroblastoma, a large portion of the cancer genome undergoes DNA methylation and histone modification, leading to silencing of tumor suppressor genes. Methylation of caspase-8[294] and that of the tumor suppressor gene *CHD5* on chromosome 1p,[223] for example, have been reported in neuroblastoma. HDAC agents have also shown preclinical activity against neuroblastoma[280,574] and are of potential therapeutic benefit because they cause apoptosis of human neuroblastoma cells, with an enhanced inhibitory effect when combined with retinoic acid.[574-577] It is thought that HDAC inhibitors potentiate the derepression of retinoid responsive genes in the presence of ligand.[578] Vorinostat, an oral class 1 and II HDAC inhibitor, has shown efficacy in solid tumor models with additive or synergistic preclinical and/or clinical activity in combination with the demethylating agent 5-aza-2-deoxycytidine (decitabine)[579] and 13-cis-retinoic acid.[580] In pediatric phase I trials, no objective responses were seen, although a complete response was seen in one patient with neuroblastoma who received the combination of retinoic acid and vorinostat.[581] Increased acetylated-H3 histones in peripheral blood lymphocytes were identified as a surrogate marker of drug target activity.[581] Based on preclinical evidence that low-dose decitabine is sufficient to induce demethylation and subsequent expression of caspase-8 in neuroblastoma cells,[582] decitabine was tested in combination with cytotoxic chemotherapy in a phase I trial.[583] Although this dose resulted in caspase-8 promoter demethylation and gene expression in bone marrow samples, the dose of decitabine capable of producing clinically relevant biologic effects were not well tolerated with cytotoxic chemotherapy in these patients. Demethylation and reexpression of melanoma antigen-encoding gene (MAGE)–1 in peripheral blood mononuclear cells as a marker of demethylation was seen in the majority of patients.[583] Decitabine has also been shown to increase the expression of other cancer/testis antigens—MAGE-A3 and NY-ESO-1—on neuroblastoma cells, facilitating cytotoxic T-lymphocyte–mediated tumor cell killing,[490,584] and forms the basis of a cancer antigen vaccine therapy for patients with relapsed neuroblastoma (NCT01241162).

EZH2 Inhibitors

MYCN has been shown to induce EZH2 expression and activity,[237,585] and therefore inhibition of EZH2 could potentially cause reexpression of tumor suppressor genes that are suppressed as a result of stimulation of EZH2 by MYCN. In neuroblastoma cells, inhibition of MYCN expression causes decreased EZH2 protein levels, which is accompanied by a decrease in global H3K27me3.[237] EZH2 inhibition was shown to cause induction of genes having tumor suppressive or differentiation-inducing capacity. Inhibition of EZH2 using small hairpin RNA knockdown or a small-molecule inhibitor of EZH2, 3-Deazaneplanocin A, led to decreased growth and induction of neurites and induction of cell death as a result of increased activated caspase-3/7 activity.[237] The small-molecule inhibitor also inhibited the growth of neuroblastoma xenografts, suggesting that this may be a potential avenue to investigate in neuroblastoma.

CONCLUSIONS AND FUTURE DIRECTIONS

The clinical heterogeneity of neuroblastoma is clearly correlated with tumor biology. The significant progress to date in understanding neuroblastoma biology has led to the ability to stratify patients and adapt treatment according to prognostic variables, resulting in a significant reduction in therapy for low- and intermediate-risk patients and the intensification of treatment for high-risk patients. A remaining challenge for low- and intermediate-risk disease is to better understand the biology of the small subset of patients who have a poor outcome and tailor their therapy accordingly. High-risk disease remains a significant clinical problem. We have likely reached the limits of dose intensification, and innovative approaches are needed to improve survival and decrease treatment-related morbidity. Future progress will likely be made by translating new discoveries regarding the underlying pathobiology of neuroblastoma into targeted therapies that can then be integrated into current treatment strategies for newly diagnosed patients. The challenge will be to determine how these individually targeted agents can be combined with cytotoxic chemotherapy, whether up front, concomitantly, or in the setting of minimal residual disease. Finally, an understanding of relapsed high-risk tumors can be achieved only by analysis of the molecular aberrations that have developed during the evolution of resistance either by direct examination of relapsed tissue or through the validation of surrogate markers.

This article describes the international neuroblastoma staging system (INSS) that is currently used in the United States.

389. Monclair T, Brodeur GM, Ambros PF, et al: The International Neuroblastoma Risk Group (INRG) staging system: an INRG Task Force report. *J Clin Oncol* 27(2):298–303, 2009.

The International Neuroblastoma Risk Group Task Force recommendation of a new staging system to improve comparison of international studies.

393. Schmidt ML, Lal A, Seeger RC, et al: Favorable prognosis for patients 12 to 18 months of age with stage 4 nonamplified MYCN neuroblastoma: a Children's Cancer Group study. *J Clin Oncol* 23(27):6474–6480, 2005.

The report of a study showing that age is a continuous prognostic variable and that the traditional cutoff of 1 year can be extended in some patients.

398. Strother DR, London WB, Schmidt ML, et al: Outcome after surgery alone or with restricted use of chemotherapy for patients with low-risk neuroblastoma: results of Children's Oncology Group study P9641. *J Clin Oncol* 30(15):1842–1848, 2012.

A Children's Oncology Group study confirming that surgery alone is adequate treatment for low-risk neuroblastoma.

405. Hero B, Simon T, Spitz R, et al: Localized infant neuroblastomas often show spontaneous regression: results of the prospective trials NB95-S and NB97. *J Clin Oncol* 26(9):1504–1510, 2008.

406. Nuchtern JG, London WB, Barnewolt CE, et al: A prospective study of expectant observation as primary therapy for neuroblastoma in young infants: a Children's Oncology Group study. *Ann Surg* 256(4):573–580, 2012.

References 405 and 406 show the feasibility of observation in infants with localized neuroblastoma.

417. Baker DL, Schmidt ML, Cohn SL, et al: Outcome after reduced chemotherapy for intermediate-risk neuroblastoma. *N Engl J Med* 363(14):1313–1323, 2010.

The first large study showing that excellent overall survival can be maintained with reduced therapy in patients with intermediate-risk neuroblastoma.

423. Kreissman SG, Seeger RC, Matthay KK, et al: Purged versus non-purged peripheral blood stem-cell transplantation for high-risk neuroblastoma (COG A3973): a randomised phase 3 trial. *Lancet Oncol* 14(10):999–1008, 2013.

A phase III randomized study showing that ex-vivo purging of stem cells does not improve outcome in patients with high-risk neuroblastoma.

432. Yanik GA, Parisi MT, Shulkin BL, et al: Semiquantitative mIBG scoring as a prognostic indicator in patients with stage 4 neuroblastoma: a report from the Children's Oncology Group. *J Nuclear Med* 54(4):541–548, 2013.

A study showing the prognostic importance of residual metaiodobenzylguanidine (MIBG)-avid disease in a large group of high-risk patients treated with a single protocol.

443. Matthay KK, Villablanca JG, Seeger RC, et al: Treatment of high-risk neuroblastoma with intensive chemotherapy, radiotherapy, autologous bone marrow transplantation, and 13-cis-retinoic acid. Children's Cancer Group. *N Engl J Med* 341(16):1165–1173, 1999.

444. Matthay KK, Reynolds CP, Seeger RC, et al: Long-term results for children with high-risk neuroblastoma treated on a randomized trial of myeloablative therapy followed by 13-cis-retinoic acid: a Children's Oncology Group study. *J Clin Oncol* 27(7):1007–1013, 2009.

The first randomized study showing efficacy of myeloablative therapy in patients with high-risk neuroblastoma (ref 443) and a follow-up study on long-term results (ref 444).

456. Ladenstein RL, Poetschger U, Luksch R, et al: Busulphan-melphalan as a myeloablative therapy (MAT) for high-risk neuroblastoma: results from the HR-NBL1/SIOPEN trial (Abstract 2). Presented at the 2011 American Society of Clinical Oncology Annual Meeting, June 3-7, 2011, Chicago, IL.

An abstract showing the superiority of Busulphan-melphalan conditioning compared with standard conditioning in a Society of Paediatric Oncology European Neuroblastoma Network (SIOPEN) trial.

469. Yu AL, Gilman AL, Ozkaynak MF, et al: Anti-GD2 antibody with GM-CSF, interleukin-2, and isotretinoin for neuroblastoma. *N Engl J Med* 363(14):1324–1334, 2010.

A randomized phase III study showing clear efficacy of anti-GD2 therapy in patients with high-risk neuroblastoma in a minimal residual disease setting.

480. Matthay KK, Yanik G, Messina J, et al: Phase II study on the effect of disease sites, age, and prior therapy on response to iodine-131-metaiodobenzylguanidine therapy in refractory neuroblastoma. *J Clin Oncol* 25(9):1054–1060, 2007.

A large phase II study showing the efficacy of metaiodobenzylguanidine (MIBG) in patients with relapsed and refractory disease.

FUTURE DIRECTIONS

Pediatric renal tumors account for approximately 5% of malignancies in children younger than 15 years old and 3.6% of malignancies in children younger than 20 years old.[1] Among 9731 patients registered with the National Wilms Tumor Study Group (NWTSG) (1969–2002), Wilms tumor (WT) composed the vast majority of childhood renal tumors (92%), followed by clear cell sarcoma of the kidney (3.4%), congenital mesoblastic nephroma (1.7%), malignant rhabdoid tumor (1.6%), and rare miscellaneous neoplasms, including primitive neuroectodermal tumor, synovial sarcoma, neuroblastoma, and cystic nephroma (1.1%). Although not historically included on NWTSG studies, renal cell carcinoma accounts for 8% of renal tumors in children from birth to 19 years, according to data from the Surveillance, Epidemiology, and End Results (SEER) program.[1]

The study of pediatric renal tumors has had a significant impact on the field of oncology. WT has provided a paradigm for multidisciplinary treatment approaches and the conduct of cooperative group studies. WT investigators took the lead in establishing one of the leading biologic-sample banks, which now contains several thousand annotated tumor, blood, and urine samples. Tenets of cancer biology, including Knudson's two-hit model and loss of imprinting in tumorigenesis, were pioneered in WT. This chapter reviews the pathology, epidemiology, genetics and biology, and treatment of pediatric renal tumors.

PATHOLOGY OF PEDIATRIC RENAL TUMORS

Staging

Stage is the major determinant of prognosis and therapy for all pediatric renal neoplasms. Two staging systems are widely used (Table 55-1). The Children's Oncology Group (COG) staging system reflects tumor extent after surgery

TABLE 55-1 Staging Systems for Pediatric Renal Tumors

	Children's Oncology Group (COG) (Prechemotherapy)	International Society of Pediatric Oncology (SIOP) (Postchemotherapy)
I	Tumor is limited to kidney and is completely resected Renal capsule intact, not penetrated by tumor No tumor invasion of veins or lymphatics of renal sinus No nodal or hematogenous metastases No prior biopsy Negative margins	Tumor is limited to kidney and is completely resected Renal capsule may be infiltrated by tumor, but tumor does not reach the outer surface Tumor may protrude or bulge into the pelvic system or ureter, but does not infiltrate Vessels of renal sinus not involved
II	Tumor extends beyond kidney but completely resected • Tumor penetrates renal capsule • Tumor in lymphatics or veins of renal sinus • Tumor in renal vein with margin not involved • No nodal or hematogenous metastases • Negative margins	Tumor extends beyond kidney but completely resected • Tumor penetrates the renal capsule into perirenal fat • Tumor infiltrates the renal sinus or invades blood and lymphatic vessels outside renal parenchyma (or both) but is completely resected • Tumor infiltrates adjacent organs or vena cava but is completely resected
III	Residual tumor or nonhematogenous metastases confined to abdomen • Involved abdominal nodes • Peritoneal contamination or tumor implants • Tumor spillage of any degree occurring before or during surgery • Gross residual tumor in abdomen • Biopsy of tumor (including fine needle aspiration) before removal of kidney • Resection margins involved by tumor	Incomplete excision of the tumor which extends beyond the resection margins (gross or microscopic residual) • Involved abdominal lymph nodes, including necrotic tumor or chemotherapy-induced changes • Tumor rupture before or intraoperatively • Tumor has penetrated the peritoneal surface • Tumor thrombi present at resection margins • Surgical biopsy before resection (does not include needle biopsy)
IV	Hematogenous metastases or spread beyond abdomen	Hematogenous metastases or spread beyond abdomen
V	Bilateral renal tumors Each side should be substaged separately according to the preceding criteria (e.g., stage V, substage II [right], substage I [left])	Bilateral renal tumors Each side should be substaged separately according to the above criteria (e.g., stage V, substage II [right], substage I [left])

before chemotherapy is given. By contrast, the International Society of Pediatric Oncology (SIOP) system reflects tumor extent after 4 to 6 weeks of chemotherapy and surgery. The COG and SIOP staging systems are applied to all pediatric renal tumors except renal cell carcinoma, for which the TNM (tumor, nodes, metastasis) system is used.[2]

The COG staging schema is very similar to that used in the National Wilms Tumor Study 5 (NWTS-5), although one change distinguishes the current COG staging criteria from the prior NWTS-5 criteria.[3,4] Localized spillage or rupture, or any form of biopsy before removal of the kidney, is no longer considered stage II but instead is considered stage III. The SIOP system was recently revised to classify tumors with local and regional lymph node involvement as stage III. Previously lymph node involvement was considered stage II, with separate designations for node-positive and node-negative disease.[5]

Wilms Tumor (Nephroblastoma)

Gross Features

WT typically presents as a unicentric, spherical mass that is sharply demarcated from the renal parenchyma.[6] Approximately 10% of WTs are multicentric, a finding that is associated with an increased likelihood of WT formation in the contralateral kidney. Approximately 5% to 6% of WTs are bilateral at presentation.

The cut surface of WT is generally pale gray and uniform, but hemorrhage, necrosis, and cyst formation are common. The texture is usually soft and friable, but stroma-rich neoplasms may have a dense, myomatous consistency. Calcification is relatively uncommon. Prominent septa frequently impart a multinodular appearance.

WT may arise anywhere in the cortex or medulla, frequently compressing and distorting renal parenchyma around its margin. Rarely exophytic tumors connected to the renal surface by a narrow stalk mimic extrarenal WT. Polypoid masses in the pelvicalyceal lumen may occur either as extensions from the primary intrarenal neoplasm or as separate neoplasms arising within the pelvic wall. The renal vein and its branches not uncommonly are filled by tumor thrombus that can extend via the inferior vena cava into the right atrium.

Cystic Variants of Wilms Tumor

Scattered cysts are commonly encountered in conventional WT, but rarely the encapsulated, well-delineated neoplasm is composed entirely of cystic spaces and delicate septa, without an expansile solid component. For neoplasms that are entirely composed of mature cells, the term is cystic nephroma (CN). If the septa contain embryonal cell types, the designation cystic, partially differentiated nephroblastoma (CPDN) is appropriate. In contrast, cystic WT is distinguished by the presence of solid, expansile regions that replace or distort the cystic spaces, rather than being passively molded by the cysts. This distinction is best made by careful examination of the gross specimen.[7]

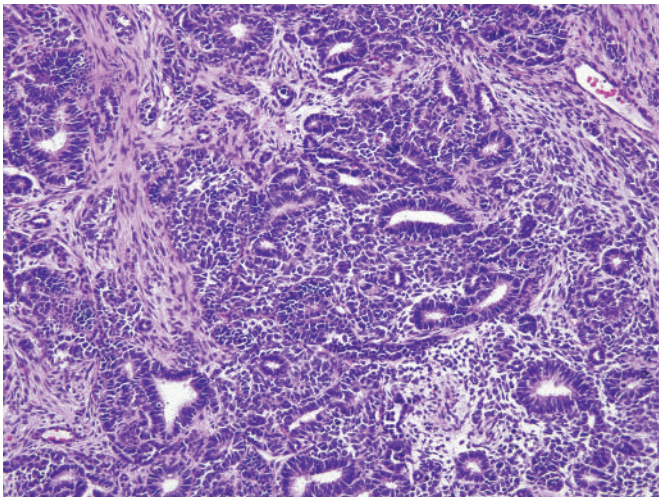

Figure 55-1 Wilms tumor, favorable histology, triphasic pattern.

CPDN has traditionally been thought to be a transitional stage in a continuum ranging from CN to WT. However recent studies show that CN is associated with *DICER1* mutations, whereas such mutations are not observed in CPDN. This suggests that the two cystic renal tumors are distinct entities.[8] The distinction of CN from CPDN has little clinical importance when the lesion has been completely resected because both lesions are curable by resection alone.

Microscopic Features

WTs are surpassed only by teratomas in their diversity of cell and tissue types and degrees of differentiation. Most WTs exhibit, at least focally, the so-called triphasic appearance, including cells of blastemal, stromal, and epithelial lineage (Fig. 55-1). However monophasic and biphasic WTs are relatively common, consisting of only one or two of these cell lineages. Each of the three major cell types can demonstrate a spectrum of patterns and degrees of differentiation, accounting for the remarkable diversity of appearances characterizing various WTs.

Blastemal Patterns. The blastemal cells of WT are small, tightly packed cells with a high nucleus-to-cytoplasm ratio, demonstrating little or no evidence of differentiation toward epithelial or stromal cell types at the light-microscopic level. Their nuclei are usually round or oval, with moderately coarse chromatin, and mold to one another in the same fashion as do the nuclei of small cell carcinoma of the lung. Nucleoli are relatively inconspicuous. Blastemal cells form several distinctive aggregation patterns, which can be divided into two broad categories, diffuse and nested, depending on their structure and degree of invasiveness. Monomorphous, relatively dyscohesive sheets of blastemal cells with aggressively invasive margins characterize the diffuse blastemal pattern. This is the most consistently aggressive pattern of WT. Stage I WTs rarely show this pattern; the majority of diffuse blastemal WT present at advanced stage, stage III or IV. Fortunately most neoplasms with the diffuse blastemal pattern are highly responsive to modern therapeutic protocols, so this pattern remains in the "favorable histology" category.[9] The diffuse blastemal pattern can be readily confused with other small blue cell tumors of childhood, and ultrastructural or other special studies may be required to establish the correct diagnosis (Fig. 55-2).

Nested blastemal patterns are characterized by sharply outlined clusters of blastemal cells in a myxoid mesenchymal background. They usually lack the invasive behavior seen with the diffuse blastemal pattern, and these neoplasms have sharply defined margins at their advancing edge. Several nested patterns may be seen. The serpentine blastemal pattern features long, serpiginous, anastomosing cords of blastemal cells in a loose, stellate, spindled stroma. This is a highly distinctive pattern of WT and helps distinguish WT from other small blue cell neoplasms of childhood. The nodular blastemal pattern resembles the serpentine pattern but has rounded blastemal nests instead of long cell cords. The basaloid blastemal pattern resembles the serpentine or nodular patterns, except that the blastemal cell clusters are outlined by a palisaded layer of cuboidal or columnar cells, reminiscent of the architecture of cutaneous basal cell carcinoma.

Epithelial Patterns. Epithelial differentiation in WT produces a variety of cell types and degrees of differentiation. Most of these recapitulate events in normal nephrogenesis (homologous differentiation). Others, such as squamous differentiation or mucinous differentiation, do not occur in the normal kidney at any stage of development (heterologous differentiation). Tubular differentiation is the most frequent epithelial pattern. This ranges from vague hints at tubular formation in blastemal foci (which may resemble rosettes) to highly differentiated tubules resembling those of the mature kidney. WTs in which tubular differentiation is predominant tend to be less aggressive, and most of these present at stage I. Although not usually invasive, tubular-predominant WTs often grow rapidly, and it is not uncommon to find huge tumors that remain confined to the kidney. Glomerular

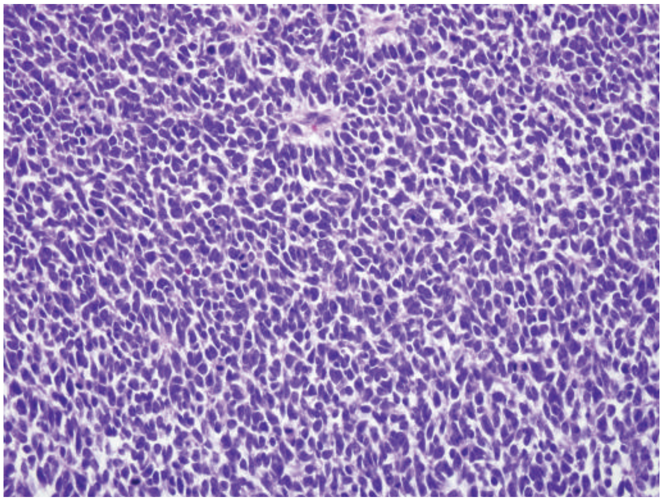

Figure 55-2 Wilms tumor, favorable histology, diffuse blastemal pattern.

differentiation, present in many WTs, ranges from simple papillary formations barely suggesting glomerulogenesis to mature tumor glomeruli closely resembling those of normal developing kidneys.

Stromal Patterns. Immature myxoid and spindled mesenchymal cells are the most common stromal cell types seen in WTs. Skeletal muscle is the most common heterologous cell type. The presence of skeletal muscle (rhabdomyoblastic differentiation) in WT must not be confused with renal rhabdoid tumor, which is discussed later in this chapter. In fact, the presence of skeletal muscle in a pediatric renal neoplasm is very strong evidence supporting the diagnosis of WT.

Anaplasia: the Sign of Unfavorable Histology in Wilms Tumor

Approximately 5% of WTs demonstrate anaplastic nuclear change, the only criterion of "unfavorable histology."[10] All WTs lacking this feature are designated as having "favorable histology." Anaplasia is almost never seen in WT diagnosed during the first year and is rare in the second year of life. The relative frequency of anaplasia increases after that age, and it is found in approximately 10% of WTs diagnosed after the age of 5 years. Anaplastic nuclear change reflects extreme polyploidy and is usually apparent under low magnification (10× objective). The features of anaplasia include (a) markedly enlarged tumor cell nuclei with increased chromatin content (hyperchromasia) and (b) multipolar mitotic figures (Fig. 55-3). The former criteria reflect polyploidy, whereas the latter criterion helps exclude degenerative nuclear changes, as are commonly seen in cells showing skeletal muscle differentiation, from the anaplastic category. Anaplasia is tightly correlated with the presence of *TP53* gene mutations.[11,12] Whereas favorable-histology WT virtually never harbors *TP53* mutations, the majority of anaplastic WTs do. At a practical level, p53 protein overexpression by immunohistochemistry correlates well but not perfectly with morphologically defined anaplasia.[13]

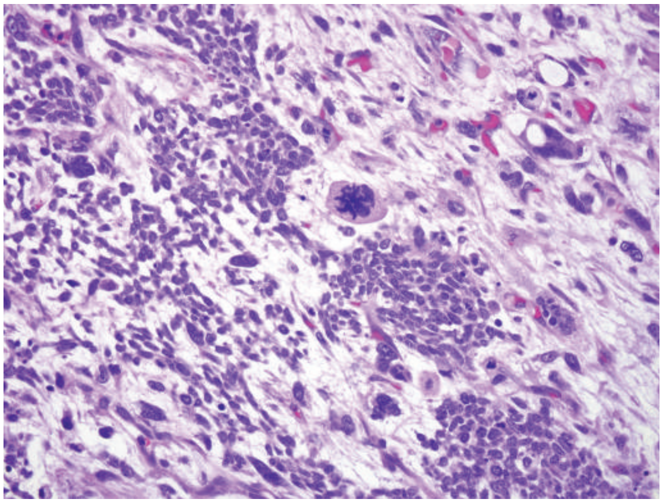

Figure 55-3 Wilms tumor, anaplastic.

Focal and Diffuse Anaplasia. Initially the presence of anaplastic nuclear changes in any region of a WT was considered prognostically unfavorable. It subsequently was suggested that anaplasia is an indicator of increased resistance to adjuvant chemotherapy and not necessarily a marker of increased tumor aggressiveness; therefore stage I anaplastic WT and WT with limited intrarenal foci of anaplasia (focal anaplasia [FA]) would be predicted to have an excellent prognosis. This concept implies that the prognosis for a patient with anaplastic WT is determined by the completeness of surgical removal of anaplastic cells.[14] However recent data on patients with stage I anaplastic WT have challenged this concept.[15] Regardless the definition of FA includes only those WTs meeting the following criteria:

1. Anaplasia is confined to one or more discrete sites within the primary tumor and is not present in extrarenal sites.
2. Tumor cells outside anaplastic foci show no "nuclear unrest" (nuclear or mitotic abnormalities that approach, but do not quite attain, the degree of severity required for a designation of anaplasia).

Any WT not meeting this definition of FA is designated as having diffuse anaplasia (DA). Any of the following situations merits assignment to the DA category:

1. Nonlocalized anaplastic change
2. Anaplastic change or nuclear unrest in invasive sites or any extrarenal deposits
3. Localized anaplastic change in a tumor that also has severe nuclear unrest elsewhere
4. Anaplasia in a random biopsy specimen
5. Anaplasia involving the edge of one or more sections, and the site(s) from which the sections were taken cannot be determined. (The latter emphasizes the importance of mapping the sections taken from a WT, best done on a photograph of a cut section of the tumor.)

Anaplastic foci are usually clearly demarcated from adjacent nonanaplastic tumor. Most cases in the FA category have a single focus of anaplasia. Anaplastic foci are usually only a few millimeters in diameter but can be larger if their localized nature can be convincingly documented.

The SIOP Postchemotherapy Histologic Classification System

Patients treated on SIOP studies receive several weeks of chemotherapy before undergoing nephrectomy. Chemotherapy usually affects necrosis of immature and actively proliferating cell types in WT, whereas slowly replicating and differentiated cell types are usually unaffected. For example, tumors composed mostly of mature skeletal muscle or renal tubules show little clinical regression with chemotherapy because so few cells are proliferating. The microscopic appearance of the tumor after chemotherapy has prognostic significance. Approximately 5% to 10% of WTs are completely necrotic after chemotherapy, a finding associated with a 98% 5-year relapse-free survival rate.[16] By contrast, WTs with a predominance of blastemal cells after chemotherapy, defined as viable cells in more than one third of the tumor mass and blastemal cells in

TABLE 55-2 Comparison of COG and SIOP Histologic Risk Classification Schemas

Children's Oncology Group (COG)	International Society of Pediatric Oncology (SIOP)
Favorable-histology Wilms tumor • No evidence of anaplasia Focal anaplastic Wilms tumor • Anaplasia confined to one or more discrete sites within the primary tumor with no extrarenal involvement • No nuclear unrest outside anaplastic foci Diffuse anaplastic Wilms tumor • Nonlocalized anaplasia • Anaplasia in invasive sites or extrarenal deposits • Localized anaplasia with severe nuclear unrest elsewhere • Anaplasia in a random biopsy specimen. • Anaplasia involving the edge of one or more sections Non–Wilms renal tumors not included in this classification schema	Low risk • Mesoblastic nephroma • Cystic partially differentiated nephroblastoma • Completely necrotic Wilms tumor Intermediate risk • Wilms tumor of epithelial, stromal, mixed, or regressive types • Focal anaplastic Wilms tumor High risk • Blastemal-type Wilms tumor • Diffuse anaplastic Wilms tumor • Clear cell sarcoma of the kidney • Rhabdoid tumor of the kidney

at least two thirds of the viable component, have relapse rates of nearly 40%.[5,17] Based on these observations, the SIOP histologic risk classification schema divides renal tumors into three risk categories: low risk, intermediate risk, and high risk. The COG and SIOP histologic classification systems are compared in Table 55-2.

Ultrastructural and Immunohistochemical Studies

Ultrastructural study is rarely necessary to establish a diagnosis of WT but can occasionally be very helpful in distinguishing blastemal WT from other undifferentiated neoplasms.[18,19] The diversity of differentiation in WT creates a correspondingly varied profile of immunohistochemical results. Blastemal cells may or may not label for vimentin and cytokeratin, whereas various differentiating elements will label according to their patterns of differentiation. For example, primitive rhabdomyoblasts within a tumor will label for the myogenic transcription factor myogenin and for cytoskeletal proteins such as actin and desmin. WT blastemal cells characteristically label for desmin but not for actin, myogenin, or other muscle markers.[20] Immunoreactivity for WT1 protein is typically limited to the blastemal and epithelial components of WT, with the stroma being negative.[21] Hence absence of labeling for WT1, particularly in a stroma-rich tumor, does not exclude the diagnosis of WT. Although WT1 immunoreactivity may help distinguish WT from PNET, it should be noted that desmoplastic small round cell tumor typically labels for WT1. Although useful, WT1 immunoreactivity cannot in and of itself establish or disprove a diagnosis of WT.

Nephrogenic Rests and Nephroblastomatosis

In more than 30% of kidneys resected for WT, the renal parenchyma contains one or more regions of persistent embryonal tissue, representing potential precursors of WT. These lesions have been given many names in the past; however, the term suggested by Dr. J. Bruce Beckwith, nephrogenic rests (NRs), is the currently accepted terminology.[22,23] The presence of multiple or diffusely distributed NRs is called nephroblastomatosis. This term is most commonly applied when the NRs are in an active state of cellular proliferation and are large enough to be apparent on imaging studies.

NRs have a dynamic life history that can yield a variety of appearances. Dr. Beckwith's classification is based on the assumption that the structure of NRs reflects both the dynamic state and the history of an individual rest. A brief summary is provided here.

Two fundamental categories of NRs are recognized, based on their topographic relation to the renal lobe. These are designated perilobar nephrogenic rests (PLNRs) and intralobar nephrogenic rests (ILNRs). ILNRs may occur anywhere in the renal lobe, including the peripheral cortex. They may also occur within the renal sinus, including in the walls of the pelvicalyceal system. ILNR have a more varied structure than do PLNRs and typically intercolate between nephrons, whereas PLNRs usually are discrete structures that are well delineated from adjacent nephrons. Rests of either major category may be further classified on the basis of their developmental fates. An individual NR may undergo any of the following fates, several of which often occur sequentially over time:

1. It may remain unchanged in size or composition, even for many years, as a tiny, microscopic blastemal focus (dormant NR).
2. It may undergo maturation, sclerosis, and eventual disappearance (sclerosing NRs and obsolescent NRs). This is the most common fate of NRs.
3. It may undergo hyperplasia, or coordinated proliferation of all susceptible cells of the rest, as distinguished from a clonal neoplastic process originating in a single cell of the rest. Hyperplastic NR may produce large, actively growing masses that have numerous mitotic figures, and a section from the interior of a hyperplastic NR may be indistinguishable from WT. Several features do help make this distinction. First diffuse hyperplastic growth, involving all or most cells of a rest, tends to preserve the original shape of the rest. When PLNRs form a continuous layer of embryonal cells at the lobar surface, hyperplastic proliferation will produce a thick "rind" of abnormal tissue at the renal surface. Ovoid and lenticular masses result from hyperplasia of NRs that originally had these shapes. An irregular-shaped, multinodular appearance will result if only some of the cells are capable of proliferation. In contrast, WT, a neoplasm presumably arising from a single cell, tends to form spherical masses. The second important feature distinguishing actively hyperplastic NRs from WT is the usual

absence of a pseudocapsule at the interface between hyperplastic NRs and the renal parenchyma.

4. Neoplastic induction is assumed to represent a clonal event originating in single cells of a rest, resulting in WT or benign adenomas. As mentioned previously rapidly growing tumors originating at a single point (or cell) will tend to grow equally in all directions, forming spherical, expansile nodules with compressed rest remnants often present at the periphery.
5. Very rarely, anaplasia may develop in nephrogenic rests.[24]

An individual rest commonly progresses through several of these processes sequentially. For example, an incipient or dormant rest may undergo hyperplasia, followed by phases of growth arrest and maturation. This will result in a large but inactive-appearing lesion. Ultimately, one or more cells within the regressing rest may be induced to form a WT.

ILNRs are most often found at the tumor-kidney interface, where they can be misinterpreted as infiltrating tumor cells or effaced by tumor compression. A helpful feature distinguishing ILNRs at the edge of a WT is the poorly defined, irregular outer border of the ILNR, which contrasts with the sharp, pushing interface between the WT and the rest within which it arose. Also ILNRs are usually less cellular than the adjacent WT that they surround.

The presence of NRs in a kidney removed for WT is correlated with an increased risk for subsequent WT formation in the remaining kidney. The type of rest and the age of the patient modify this risk.[25] When a carefully sampled kidney is free of rests, the risk of contralateral WT is extremely low. The possibility of subsequent WT developing in the remaining kidney should be considered in planning the follow-up of patients whose nephrectomy specimen reveals the presence of NRs in addition to WT.

Differential Diagnosis of Wilms Tumor

Triphasic Wilms Tumor. The triphasic pattern rarely presents a problem in diagnosis, except when small biopsies are obtained from large retroperitoneal masses of uncertain origin. In this setting other mixed neoplasms might deserve consideration, including teratoma, hepatoblastoma, pancreatoblastoma, teratoma, mesothelioma, synovial sarcoma, and intraabdominal desmoplastic small round cell tumor. In the absence of nephrogenic differentiation or the distinctive nested blastemal patterns described previously, ancillary studies such as immunohistochemistry, molecular biology, or electron microscopy may be required to distinguish some of these lesions from WT. WT with extensive heterologous differentiation ("teratoid WT") is easily confused with immature teratoma. Renal teratomas are extremely rare, and some of the reported cases likely represent teratoid WT.

Blastemal Wilms Tumor Versus Other Small Blue Cell Tumors of Childhood. The problem of distinguishing blastemal WT from other small blue cell tumors is most likely to arise when dealing with biopsies from metastatic sites or from large abdominal tumors of uncertain origin. The distinctive aggregation patterns of blastemal WT, the presence of nuclear molding, or the focal presence of tubular differentiation will often reveal the diagnosis. Early tubular differentiation in WT lacks lumens and therefore can sometimes be confused with rosettes of neuroblastoma or primitive neuroectodermal tumor (PNET). The presence of true lumens even focally confirms tubular differentiation, whereas neurofibrils are diagnostic of a neuroblastic pseudorosette. Neuroblastic rosettes do rarely occur in WT, but usually only in teratoid WTs, which are not likely to be confused with neuroblastomas or PNETs. Immunohistochemistry, electron microscopy, molecular diagnostic techniques, cytogenetics, circulating tumor markers, and other special studies are often required to confirm the nature of a small blue cell tumor.

Epithelial Predominant Wilms Tumor Versus Papillary Renal Cell Carcinoma. The challenge of distinguishing epithelial predominant WT from papillary renal cell carcinoma (PRCC) is most often encountered in tumors from adolescents or adults. Papillary adenoma, the benign precursor of PRCC, may resemble epithelial predominant NRs, and epithelial predominant WTs can have a predominantly papillary architecture. Sometimes PRCCs have a predominant tubular or solid component. Molecular or cytogenetic studies may be helpful because PRCC characteristically contains increased copies of chromosomes 7 and 17 and, in tumors from male patients, deletion of Y.[26] Unequivocal glomerular differentiation, characteristic blastemal aggregation patterns, or the presence of heterologous cell types can confirm the diagnosis of WT. Immunoreactivity for cytokeratin 7 has been advocated as a useful marker for PRCC, but focal positive labeling for this marker occurs in many WTs. Only when diffusely positive is cytokeratin 7 labeling likely to be discriminatory. Nuclear labeling for WT1 protein may distinguish WT, NRs, and metanephric adenoma from PRCC, insofar as only the latter does not label.[27]

Clear Cell Sarcoma of the Kidney

Gross Appearance

Clear cell sarcoma of the kidney (CCSK) is always unicentric, with a distinct tumor-kidney junction. Tumors are usually relatively large, with a mean specimen diameter of approximately 11 cm.[28] The cut surface is often glistening and gelatinous. Cysts are almost always present and may be so prominent as to suggest cystic nephroma on gross examination or imaging studies.

Microscopic Appearance

Under low magnification, most CCSKs appear monomorphous, without the prominent lobulation usually seen in WT. CCSK usually has a scalloped border that appears fairly sharp under low power. Under higher magnification, the border appears less sharply defined because of the penetration of neoplastic cells a short distance into the surrounding kidney or the tumor capsule. This growth pattern tends to surround and isolate individual single nephrons, which is rarely if ever seen with WT. The entrapped tubules are usually confined to the peripheral 2 to 3 cm of a CCSK. Their epithelium commonly shows embryonal metaplastic changes similar to those entrapped in congenital mesoblastic nephroma, and the resultant basophilic epithelium creates confusion with WT. Dilation of these entrapped tubules produces intratumoral cysts that may mimic cystic nephroma. CCSK may show a wide variety of morphologic patterns, described in the subsequent sections.[28-31]

Classic Pattern. The hallmark of the classic pattern is an evenly distributed network of vascular septa, which has a branching, "chicken-wire" pattern similar to that seen in myxoid liposarcoma or oligodendroglioma. These fibrovascular septa subdivide the tumor into a conspicuous pattern of cords and nests, averaging six to ten cells in width, composed of polygonal cells that usually lack distinct cytoplasmic borders. Cells within the cords are less densely packed than those of blastemal WT, and overlapping nuclei are less frequent. Nuclear chromatin is usually finely granular, with inconspicuous nucleoli (Fig. 55-4). In well-fixed specimens, the fine nuclear chromatin pattern is the most helpful clue to the diagnosis. However, it is influenced markedly by the timing and type of fixation. Mitotic figures are variable in number but are usually less numerous than those in WT. The cytoplasm usually lacks distinct borders and is surrounded by extracellular mucopolysaccharides, which creates the illusion of clear cytoplasm.

CCSK is easily confused with other neoplasms because the classic pattern is often modified, presenting alterations that mimic other neoplasms to a sometimes striking degree. Fortunately the classic pattern of CCSK predominates in most specimens and is present at least focally in more than 90% of tumors. However the pathologist who is unaware of these variant patterns is likely to diagnose CCSK as another neoplasm, with different therapeutic and prognostic implications. These variant patterns are described in the subsequent sections.[28-30]

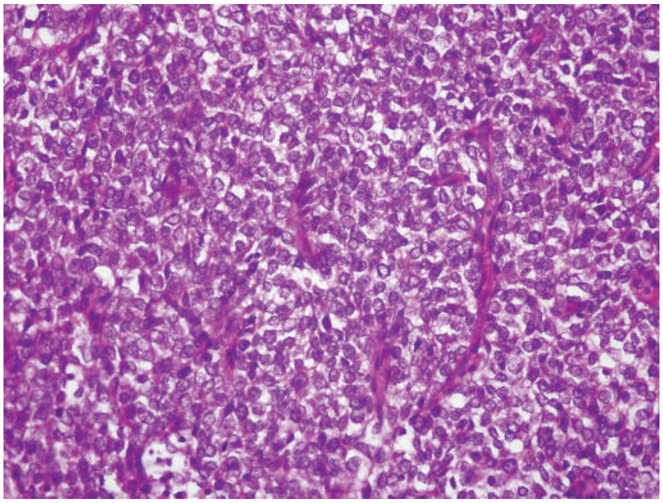

Figure 55-4 Clear cell sarcoma of the kidney.

Epithelioid Patterns. Condensation of cord cells of the classic CCSK pattern creates striking epithelioid arrangements in approximately 15% of cases.[28] These condensations usually form trabeculae or rosettes. These epithelioid formations conform to the pattern of the original cell cords and can be either straight or undulating in configuration. The epithelioid variants of CCSK are most likely to be mistaken for WT. In all of the examples analyzed by immunohistochemistry, these epithelioid formations have been negative for epithelial markers, in contrast to the epithelial cells of WT.

Spindle Cell Patterns. Spindle cell patterns are observed in approximately 10% of cases and result from two mechanisms.[28] Proliferation of septal cells produces wide spindle cell septa that compress or obliterate the cell cords. Intersections of these hyperplastic septal cells often resemble the storiform patterns seen with fibrohistiocytic neoplasms. Spindled transformation of cord cells yields a spindled pattern with preservation of thin fibrovascular septa.

Myxoid and Sclerosing Patterns. Most CCSKs contain abundant mucopolysaccharide, apparently produced by the cord cells.[28] This material separates cord cells and creates the appearance of clear cytoplasm. In approximately 30% of cases, mucopolysaccharide occupies more volume than the neoplastic cells themselves and forms large pools or cystic spaces.[28] While it accumulates, the tumor cells become progressively more isolated and eventually degenerate. In time the mucoid material becomes denser, eosinophilic, and hyaline in appearance. Hyaline sclerosis is found in 35% of CCSK. Complete replacement of cell cords by hyaline sclerosis preserves the original cord pattern with retention of the vascular septa, preserving the chicken-wire appearance. More diffuse zones of dense stromal sclerosis surrounding individual tumor cells may create an osteosarcoma-like appearance. Dense stromal sclerosis is relatively uncommon in untreated WT, and this finding can be a clue to the diagnosis of CCSK or rhabdoid tumor in limited biopsy material.

Palisading (Verocay-Body) Pattern. Nuclear palisading resembling schwannoma is focally prominent in approximately 10% of CCSK specimens.[28] Unlike schwannomas, these areas are not immunoreactive for S-100 protein.

Monstrocellular (Anaplastic) Pattern. Approximately 3% of CCSK contain foci with enlarged, pleomorphic nuclei and bizarre mitotic figures, resembling the appearance of anaplastic WTs or pleomorphic sarcomas. This is the only pattern of CCSK that frequently overexpresses p53 protein.[28]

Posttherapy Patterns. Recurrences of CCSK after therapy may have a deceptively hypocellular and bland appearance, suggesting low-grade fibromatosis or myxoma. A lump appearing anywhere in a child with a history of CCSK should be viewed as a potential metastasis until proven otherwise.

Ultrastructure, Immunohistochemistry, and Cytogenetics

Ultrastructural studies yield few clues as to the putative cell of origin of CCSK.[32] The tumor cells are characterized by a high nuclear-to-cytoplasmic ratio, with nuclear shapes that are more irregular and variable than would be expected from light microscopy. The cytoplasm is usually tenuous, with elongated, irregular processes surrounding abundant intercellular matrix. This latter feature is responsible for the vacuoles often seen with the light microscope. The cytoplasm tends to be poor in organelles. Immunohistochemistry has afforded little new insight into the histogenesis of CCSK, except to exclude various potential lines of differentiation for this enigmatic neoplasm. Vimentin is positive in nearly all specimens and BCL2 in some, but other markers are consistently negative. These include stains for epithelial markers (cytokeratins and epithelial membrane antigen [EMA]), neural markers (S-100 protein), neuroendocrine markers (chromogranin, synaptophysin), muscle markers (desmin), CD34, CD117 (c-kit), and CD99 (MIC2).[28] A subset of CCSK harbor a t(10;17)(q22;p13) chromosome translocation, resulting in a *YWHAE-FAM22* gene fusion.[33]

Differential Diagnosis of Clear Cell Sarcoma of the Kidney

The distinction of CCSK from other renal neoplasms can be extremely difficult, even for those with extensive experience in pediatric renal neoplasm pathology. The distinction of CCSK from rhabdoid tumor of the kidney is covered in the section on the latter. The major differential diagnostic concerns are discussed in the text that follows.

Clear Cell Sarcoma of the Kidney Versus Wilms Tumor. Some blastemal WT are richly vascular, and the vascular pattern may perfectly mimic that of CCSK. Several features help in this differential diagnosis. First, under low magnification, blastemal WTs often show distinctive nested patterns, whereas CCSKs are not typically nested. Second, blastemal WTs are more densely cellular than are CCSKs. When cells are closely packed, most nuclei are overlapping, and nuclei mold to one another, WT is more likely than CCSK. Third, heterologous tissues such as skeletal muscle are never seen in CCSK. The presence of a focus resembling CCSK in an otherwise unequivocal WT can safely be ignored. Fourth, multicentricity is common in WT, whereas multicentric and bilateral CCSKs have not been reported. Fifth, sclerotic, hyalinized stroma in an untreated tumor favors CCSK over WT. Finally, a fine nuclear chromatin pattern favors a diagnosis of CCSK over WT, although this feature is susceptible to fixation and processing artifacts.

Clear Cell Sarcoma of the Kidney versus Congenital Mesoblastic Nephroma. Cellular congenital mesoblastic nephroma (CMN) may resemble spindled variants of CCSK, and the age ranges of these two entities overlap. Small foci resembling CCSK may occur in CMN, but CMN lacks the diversity of morphologic patterns that typifies CCSK. The absence of the t(12;15) chromosome translocation that is characteristic of cellular CMN in all CCSKs examined to date indicates that these two neoplasms are unrelated.

Congenital Mesoblastic Nephroma

Gross Appearance

CMN arises unicentrically and usually appears to have arisen deep within the medial parenchyma, near the renal sinus. The renal sinus and adjacent structures on the medial side of the kidney are major sites of extrarenal spread of CMN. Surgeons and pathologists must pay particular attention to the medial margin of the CMN resection specimen. However because of the predominance of freely mobile fat in this location and retraction artifact, the medial specimen margin is notoriously difficult to evaluate, and it is rarely possible to be certain that it is free of involvement by CMN.

The appearance of the sectioned surface of CMN is variable and depends on the subtype. Classic CMNs have a tough, whorled appearance resembling that of leiomyoma, but cellular CMNs may be soft, friable tumors. Hemorrhage, necrosis, and cyst formation are present to some degree in a majority of cellular CMNs.

Microscopic Appearance

CMN is a low-grade fibroblastic sarcoma of the infantile kidney. The classic type of CMN has a fibrous, whorled gross appearance. Morphologically, classic CMN is identical to infantile fibromatosis; it is composed of bland fibroblastic or myofibroblastic cells, arranged in fascicles that dissect into the native kidney (Fig. 55-5).[34] Mitoses are usually rare, and necrosis is absent. The leading edge of the tumor characteristically induces angiomatous vascular proliferation where it abuts perirenal fat. Entrapped renal tubules may acquire a primitive appearance (embryonal metaplasia), which may cause confusion with true neoplastic tubular differentiation that would suggest a diagnosis of biphasic stromal-epithelial WT. In contrast, the cellular variant of CMN typically has a softer, more fleshy and hemorrhagic appearance with necrosis and cystification. Microscopically, cellular CMN is identical to infantile

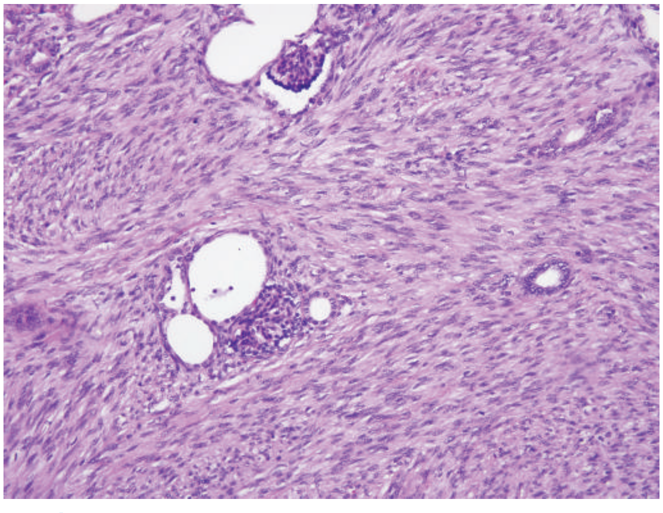

Figure 55-5 Congenital mesoblastic nephroma, classic type.

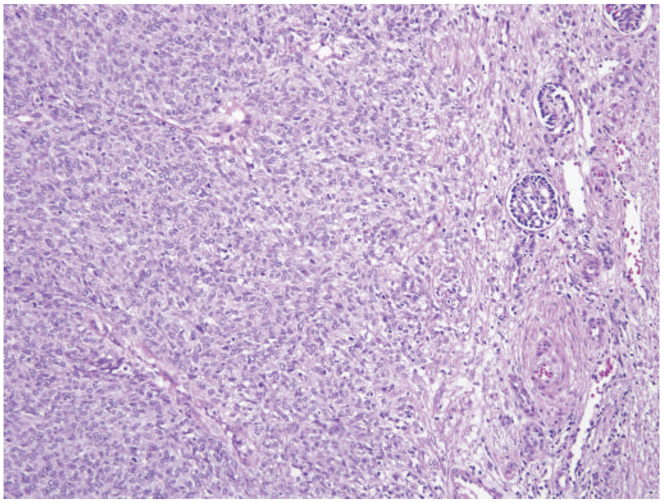

Figure 55-6 Congenital mesoblastic nephroma, cellular type.

fibrosarcoma (IFS).[35] Compared with the classic variant, cellular CMNs more often have a "pushing" border, demonstrate sheetlike growth patterns, are less often fascicular, are more cellular, and have a higher mitotic rate (Fig. 55-6). Tumor cells may be polygonal with well-demarcated pink cytoplasm and nuclei with vesicular chromatin and prominent nucleoli; this raises the differential diagnosis of rhabdoid tumor of the kidney. Alternatively the tumor cells may be thinner, primitive, and spindled, yielding a more embryonal "blue cell" appearance. Mixed CMNs have areas identical to both cellular and classic CMN in varied proportions within the same tumor.

Immunohistochemistry and Ultrastructure

Immunohistochemistry is of limited value in the diagnosis of CMN. The cells of CMN label in a fashion consistent with fibroblasts or myofibroblasts.[36] Whereas actin may be focally positive, desmin and CD34 are typically negative (P. Argani, unpublished observations). INI1 protein is retained. Ultrastructural studies also reveal features consistent with fibroblasts or myofibroblasts.[37] Most CMN cells show abundant rough endoplasmic reticulum with branching and anastamosing profiles, and primitive cell junctions are often found.

Differential Diagnosis of Congenital Mesoblastic Nephroma

The differential diagnosis for CMN includes stromal-predominant WT, CCSK, metanephric stromal tumor (MST) and malignant rhabdoid tumor (MRT). These distinctions are crucial because most children with CMN do not require adjuvant chemotherapy, whereas those with WT, CCSK, and MRT are treated on specific chemotherapy protocols. Features that distinguish CCSK and MRT from CMN are covered in the sections on CCSK and MRT, respectively. The features that distinguish CMN from WT and MST are expanded on in the subsequent sections.

Congenital Mesoblastic Nephroma Versus Wilms Tumor. As mentioned previously, embryonal metaplastic changes in nephrons surrounded by CMN cells are sometimes misinterpreted as tubular or papillary elements in a WT. Rarely untreated WT will be composed predominantly of stromal cells. In most of these the presence of immature or mature skeletal muscle readily excludes the diagnosis of CMN. Specimens removed after chemotherapy are particularly challenging. Treatment often ablates the embryonal, proliferating elements of a WT but tends to spare stromal cells. The resulting appearances can readily be confused with CMN. The following features are helpful in the differential diagnosis:

1. A diagnosis of CMN should be considered suspect in a patient who has received prior therapy, unless the clinical and pathologic features are characteristic.
2. Most CMNs are diagnosed in the first 3 months of life, whereas WT is relatively uncommon at this age. Only 10% of CMNs are diagnosed after 1 year, and virtually none are diagnosed after 2 years.
3. Most WTs express a diversity of cell types and tissue patterns. In contrast blastemal foci do not occur in a CMN, and skeletal muscle is never seen. However nodules of entrapped cartilage and squamous pearls may occur in CMN (likely reflecting coexisting renal dysplasia), and this should not be taken as evidence for WT.
4. The interdigitating, irregular border of classic CMN distinguished it from most WTs. However, cellular CMN often has a sharp, pushing border, similar to that of most WTs.
5. Bilaterality or the presence of NRs (or both) strongly favors WT over CMN.

Congenital Mesoblastic Nephroma Versus Metanephric Stromal Tumor. Many tumors previously considered to be CMNs in children older than age 3 years are in fact distinct from CMN and represent the newly recognized entity MST.[38] MST is identical to the stromal component of metanephric adenofibroma [39] (previously known as nephrogenic adenofibroma),[40] a biphasic tumor containing an epithelial component that is identical to metanephric adenoma. MST is a benign lesion composed of spindled to stellate cells featuring thin hyperchromatic nuclei and thin indistinct cytoplasmic extensions. Several of the characteristic features of MST distinguish it from CMN. MST characteristically surrounds and entraps renal tubules and blood vessels to form concentric "onion-skin" rings or collarettes around these structures. Most MSTs induce angiodysplasia of entrapped arterioles, consisting of epithelioid transformation of medial smooth muscle and myxoid change. One fourth of MSTs feature juxtaglomerular cell hyperplasia within entrapped glomeruli, which may occasionally lead to hypertension associated with hyperreninism. Finally, unlike CMNs, MSTs are typically immunoreactive for CD34, but labeling may be patchy.

Malignant Rhabdoid Tumor of the Kidney

Gross Appearance

Most MRTs are relatively small because metastasis occurs early in the evolution of the neoplasm. On gross

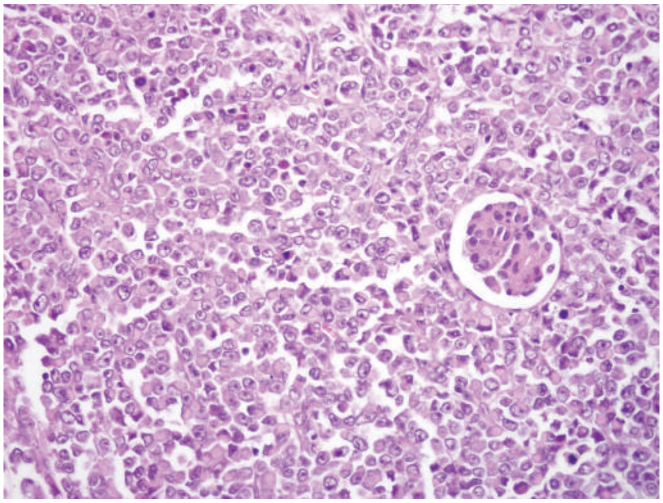

Figure 55-7 Malignant rhabdoid tumor of the kidney.

examination MRTs are typically fleshy or hemorrhagic neoplasms, with ill-defined borders and frequent satellite nodules that reflect the tumor's highly invasive nature.[41]

Microscopic Appearance

MRT was so named because of the resemblance of the tumor cells to rhabdomyoblasts. However this highly lethal infantile neoplasm does not demonstrate muscle differentiation. Microscopically these neoplasms typically engulf native renal elements at their periphery and demonstrate extensive vascular invasion. MRT classically consists of sheets of monotonous cells featuring a characteristic cytologic triad: vesicular chromatin, prominent nucleoli, and hyaline cytoplasmic inclusions (Fig. 55-7). These features are variably well developed within a given tumor, which means that it may be necessary to examine multiple microscopic fields from many sections to find them.

Ultrastructure and Immunohistochemistry

Ultrastructurally the cytoplasmic inclusions correspond to whorled intermediate filaments.[42] The whorled filaments may trap antibodies used for immunohistochemistry, yielding a nonspecific polyphenotypic pattern. With this caveat, strong vimentin and focal EMA labeling are characteristic immunohistochemical findings. Recently, an immunohistochemical assay for INI1 protein has become available. Loss of INI1 protein expression reflects *INI1* genetic status and, within the kidney, is a sensitive and nearly specific marker for MRT.[43]

Differential Diagnosis of Rhabdoid Tumor of the Kidney

The diagnosis of MRT is often challenging because a wide variety of renal and extrarenal tumors of adult and children may feature fully developed "rhabdoid" cytology, at least focally.[44,45] In the pediatric kidney these include cellular CMN (of the plump cell type), CCSK, blastemal WT, PNET, renal medullary carcinoma, and rhabdomyosarcoma.[44] In general, thorough sampling of such tumors is most helpful, insofar as it typically reveals specific differentiation that excludes MRT. Additionally, the age of the patient is very helpful because MRT is not seen outside of early childhood. Finally, in the kidney loss of INI1 protein expression by immunohistochemistry is highly specific for MRT or renal medullary carcinoma.[46] Several specific differential diagnoses are covered in the subsequent sections.

Malignant Rhabdoid Tumor Versus Wilms Tumor. Both blastemal and myogenic elements of WT may contain cytoplasmic inclusions resembling those of MRT. A distinctive serpentine blastemal pattern, other distinctly nephrogenic features, or heterologous cells such as skeletal muscle supports the diagnosis of WT. The prominent nucleoli characteristic of MRT are not typically seen in WT, with the exception of some anaplastic specimens.

Malignant Rhabdoid Tumor Versus Cellular Congenital Mesoblastic Nephroma. The plump cell variant of cellular CMN often has vesicular nuclei with prominent nucleoli, and a rare CMN contains foci with hyaline cytoplasmic inclusions. A predominance of spindled patterns and a less invasive tumor periphery favor a cellular CMN over a rhabdoid tumor. Cytogenetic or molecular analysis (or both) may be invaluable in this setting; demonstration of chromosome 22q loss or loss of INI1 protein expression by immunohistochemistry supports MRT, whereas the presence of the ETV6-NTRK3 gene fusion supports cellular CMN.

Malignant Rhabdoid Tumor Versus Clear Cell Sarcoma of the Kidney. CCSK may rarely show prominent nucleoli, which can lead to difficulty in distinguishing CCSK from MRT. The presence of classic cytologic features of CCSK elsewhere and the presence of characteristic CCSK patterns are the major clues to the correct diagnosis in such instances. CCSKs lack the extreme invasiveness of MRTs and are generally more subtly invasive neoplasms.

Renal Carcinomas in Children

All of the common renal cell carcinomas (RCCs) of adulthood (clear cell, papillary, chromophobe, and collecting duct) may occasionally affect the pediatric kidney, but the clinical and differential diagnostic considerations differ in this setting. Children with von Hippel-Lindau syndrome are predisposed to develop conventional (clear cell) RCC. Children with tuberous sclerosis are at increased risk for developing both RCC and epithelioid angiomyolipoma,[47] and immunohistochemical analysis may be needed to distinguish these two. As discussed previously, PRCC may overlap morphologically with epithelial predominant WT or metanephric adenoma. However most pediatric RCCs represent distinctive neoplastic entities. Four of these entities are described in the subsequent sections.

Xp11.2 Translocation Renal Cell Carcinomas

RCCs with chromosome translocations involving Xp11.2 and resulting gene fusions involving the *TFE3* transcription factor gene were officially recognized in the 2004 World Health Organization Renal Tumor Classification.[48] Although this subtype of RCC is relatively uncommon on

TABLE 55-3 MiTF/TFE Translocation Neoplasms

Gene Fusion	Chromosome Translocation	Age (Years)	Tumor
ASPL-TFE3	der(17)t(X;17)(p11.2;q25)	5-40	ASPS
ASPL-TFE3	t(X;17)(p11.2;q25)	2-68	RCC
PRCC-TFE3	t(X;1)(p11.2;q21)	2-70	RCC
PSF-TFE3	t(X;1)(p11.2;p34)	5-68	RCC
NoNo-TFE3	inv(X)(p11;q12)	39	RCC
CLTC-TFE3	t(X;17)(p11.2;q23)	14	RCC
Alpha-TFEB	t(6;11)(p21;q12)	6-53	RCC

ASPS, Alveolar soft part sarcoma; *RCC*, renal cell carcinoma.

a percentage basis in adults, it most likely accounts for the majority of pediatric RCCs. One distinctive subtype bears a t(X;17)(p11;q25), which results in the identical *ASPL-TFE3* gene fusion, as was initially identified in alveolar soft part sarcoma (ASPS), and has been designated the *ASPL-TFE3* RCC.[49] Other subtypes are listed in Table 55-3.

Xp11.2 translocation RCCs closely resemble conventional (clear cell) renal carcinomas on gross examination, usually being tan-yellow and often necrotic and hemorrhagic. A papillary carcinoma composed of clear cells is the most distinctive histopathologic appearance (Fig. 55-8), because this combination is uncommon in other defined types of renal carcinomas. However the Xp11.2-translocation RCCs often have nested architecture and often contain cells with granular eosinophilic cytoplasm. The histologies of Xp11-translocation RCC associated with different *TFE3* gene fusions differ. The *ASPL-TFE3* RCCs feature cells with voluminous, clear to eosinophilic cytoplasm, discrete cell borders, vesicular nuclear chromatin, and prominent nucleoli. In contrast, the *PRCC-TFE3* RCCs, characterized by a t(X;1)(p11.2; q21), typically have less abundant cytoplasm; fewer psammoma bodies; fewer hyaline nodules; and a more nested, compact architecture.[50]

Renal carcinomas with Xp11.2-associated translocations characteristically underexpress epithelial immunohistochemical markers such as cytokeratin and epithelial membrane antigen. Only approximately one half of cases will be positive with these markers, and the labeling is often focal. Vimentin immunoreactivity is also often focal compared with that of the adjacent blood vessels; this also differs from conventional RCCs, which are diffusely positive. Rare Xp11.2-translocation carcinomas, especially ones with variant gene fusions such as *PSF-TFE3* and *CLTC-TFE3*,[51] express melanocytic markers HMB45 and Melan A, creating confusion with epithelioid angiomyolipoma. Cathepsin K, a serine protease normally expressed in osteoclasts, is expressed in approximately 50% of translocation RCC but no other subtype of RCC.[52,53] The most distinctive immunohistochemical feature of these neoplasms is nuclear labeling for TFE3 protein using an antibody to the C-terminal portion of TFE3, which is retained in the gene fusions. Nuclear labeling for TFE3 is a common feature of all Xp11.2-translocation RCC and ASPS but does not occur in other RCCs (Fig. 55-9). Because native TFE3 is known to be ubiquitously expressed but is not detectable in normal tissues by immunohistochemistry, it is postulated that the different *TFE3* gene fusions consistently lead to overexpression of the fusion protein relative to native TFE3, such that the protein becomes detectable by this assay.[54] However TFE3 immunohistochemistry is difficult to optimize in the setting of variable fixation, and a break-apart fluorescence in situ hybridization (FISH) assay for *TFE3* gene rearrangements is a more reliable assay in formalin-fixed, paraffin-embedded tissue.[55]

When analyzed by electron microscopy, Xp11.2-associated carcinomas feature cell junctions, microvilli, intracytoplasmic fat, and glycogen and thereby most closely resemble conventional renal carcinomas. However a subset of cases demonstrates distinctive ultrastructural

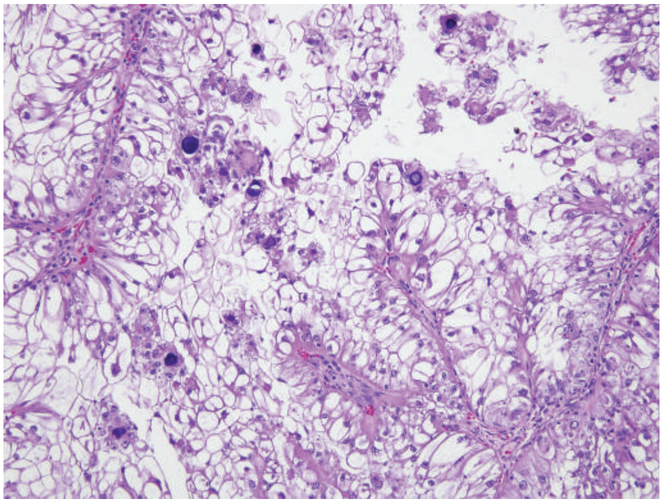

Figure 55-8 Xp11.2 translocation renal cell carcinoma.

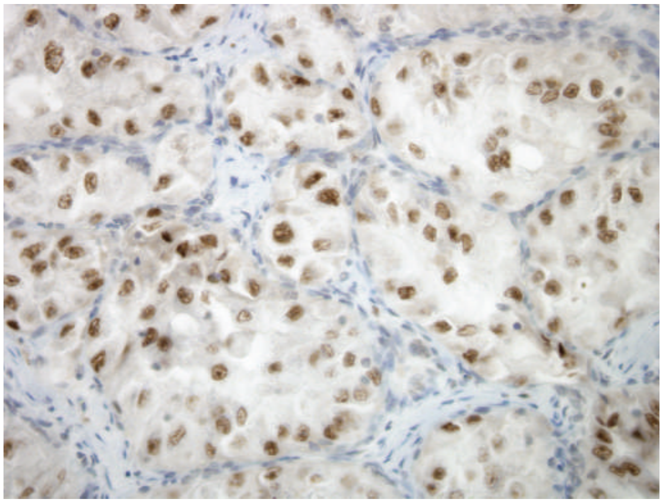

Figure 55-9 Xp11.2 translocation renal cell carcinoma, TFE3 immunohistochemistry.

features. Most of the *ASPL-TFE3* RCCs contain membrane-bound cytoplasmic granules, and a few have membrane-bound rhomboidal crystals that are identical to those seen in soft tissue ASPS. Some *PRCC-TFE3* RCCs have had distinctive intracisternal microtubules similar to those seen in malignant melanoma and extraskeletal myxoid chondrosarcoma.

t(6;11)(p21;q12) Renal Cell Carcinomas

Another distinctive type of RCC bears a t(6;11)(p21;q12). The distinctive clinicopathologic features of these neoplasms were not described until 2001.[56] On microscopic examination these neoplasms usually feature nests and tubules of polygonal epithelioid cells, separated by thin capillaries. Some cases have had papillary formations. The majority of the tumor cells have abundant clear to granular eosinophilic cytoplasm, well-defined cell borders, and round nuclei with small nucleoli. However a second population of smaller epithelioid cells is also characteristic, typically (but not always) clustered around nodules of hyaline basement membrane material within larger acini (Fig. 55-10). The cases examined have generally been negative for cytokeratins by immunohistochemistry, but almost all have labeled at least focally for HMB45, Melan A, and Cathepsin K, again creating confusion with epithelioid angiomyolipoma.

The t(6;11)(p21;q12) has been shown to result in a fusion of the intronless, untranslated *Alpha* gene with *TFEB,* a gene belonging to the same transcription factor family as *TFE3*.[57,58] The consequence of the *Alpha-TFEB* fusion is dysregulated expression of the normal full-length TFEB protein. Along these lines, the t(6;11) RCCs (also known as *Alpha-TFEB* RCCs) demonstrate specific nuclear labeling for TFEB protein by immunohistochemistry (IHC), whereas other neoplasms and normal tissues do not (Fig. 55-11). Hence nuclear labeling for TFEB is a sensitive and specific diagnostic marker for this neoplasm with a *TFEB* gene fusion, just as nuclear labelling for TFE3 is a sensitive and specific marker for neoplasms bearing *TFE3* gene fusions.[59] A break-apart FISH assay for *TFEB* gene rearrangements has recently been developed for formalin-fixed, paraffin-embedded tissue and is proving to be more sensitive than TFEB IHC assay.[60]

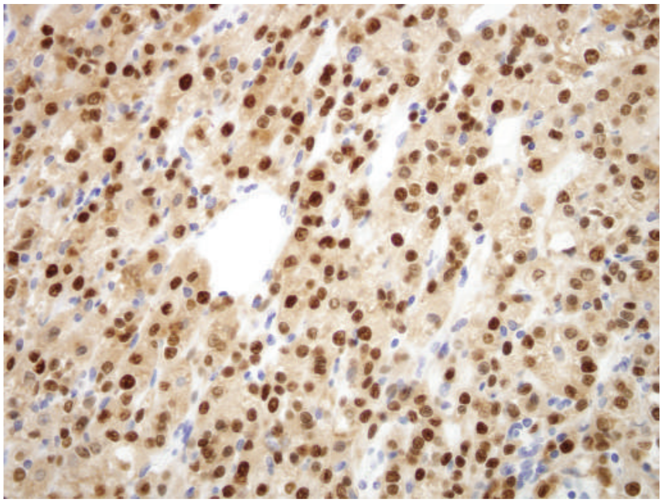

Figure 55-11 Renal cell carcinoma with t(6;11) (p12:q12) translocation, transcription factor EB immunohistochemistry.

Renal Medullary Carcinoma

Renal medullary carcinoma (RMC) was first described in 1995 by Davis and colleagues as “the seventh sickle cell nephropathy.”[61] These tumors characteristically affect young patients (mean age, 22 years) with sickle cell trait. Tumors are typically centered in the renal medulla but demonstrate an aggressively infiltrative growth pattern with frequent vascular permeation. The tumor cells feature vesicular chromatin and prominent nucleoli, frequently associated with hyaline intracytoplasmic inclusions, therefore imparting a rhabdoid cytologic appearance. The tumor cells of RMC demonstrate diffuse (sheetlike), cribriform, gland-forming, microcystic, or reticular growth patterns, the latter two simulating yolk-sac tumor (Fig. 55-12). The stroma is typically desmoplastic and

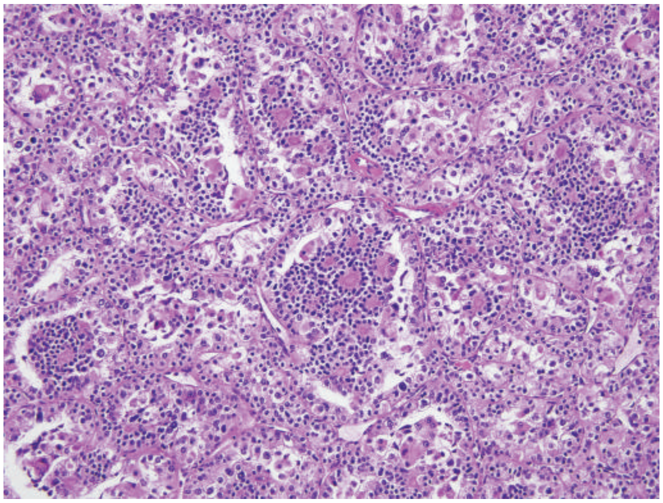

Figure 55-10 Renal cell carcinoma with t(6;11) (p12;q12) translocation.

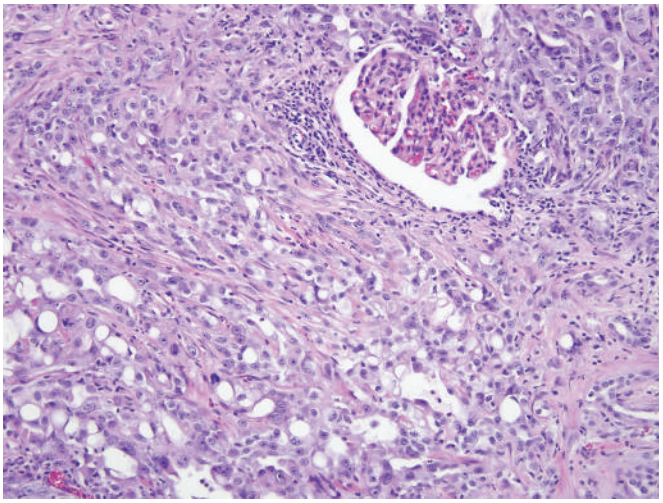

Figure 55-12 Renal medullary carcinoma.

infiltrated by neutrophils, and close examination of extravasated red blood cells may reveal sickling. However, hemoglobin electrophorosis is more reliable than the latter for determining that the patient has sickle cell trait. These tumors frequently present at high stage and are highly lethal; Davis and colleagues reported a mean survival of only 15 weeks. Given their medullary epicenter and high-grade cytology, RMCs are considered by some to be variants of collecting duct carcinoma, although the latter entity is a notoriously elusive one to define. As noted previously, RMCs consistently show loss of expression of INI-1 protein by IHC, similar to RTK.

Oncocytic Renal Carcinomas in Neuroblastoma Patients

Meideros and coworkers have described oncocytic renal carcinomas arising in children who had previously had neuroblastoma.[62] The genetic alterations identified in these lesions did not match those of known renal carcinomas, suggesting that these are another distinctive entity.

Primitive Neuroectodermal Tumor of Kidney

Primary renal PNET should be considered in the differential diagnosis of any undifferentiated blue cell tumor of the kidney. This neoplasm is encountered mainly in adolescent and young adult patients and tends to present at advanced stage.[63] Tumors consist of sheets of undifferentiated small blue cells with frequent necrosis and occasional rosettes. Renal PNETs are frequently mistaken for blastemal WTs of adolescent or adult patients and might account for some of the adverse prognosis attributed to "adult WT." Compared to WT, tumor cell nuclei are less hyperchromatic and more evenly placed. Molecular detection of the *EWS-FLI1* gene fusion that results from the characteristic and specific t(11;22)(q24;q12) chromosome translocation is a useful way to confirm the diagnosis of PNET in suspected cases.[64] Also helpful is immunohistochemical labeling for CD99; the characteristic membrane staining pattern observed in PNETs is rarely if ever observed in WT blastemal cells or cellular CCSKs, which are the main differential diagnosis.[65]

Synovial Sarcoma of the Kidney

Similar to renal PNET, primary renal synovial sarcoma has been established as a distinctive neoplastic entity by demonstration of its specific chromosome translocation and gene fusion.[66,67] Genetically confirmed cases have affected young adults. Many have previously been classified as adult blastemal WT, embryonal sarcoma of the kidney, adult cellular mesoblastic nephroma, or sarcoma arising in cystic nephroma. Renal synovial sarcomas are typically large and often cystic, and they present at advanced stage. The typical appearance is that of a monomorphic, highly cellular neoplasm composed of plump, spindled cells growing in short fascicles. Tumor cells have ovoid nuclei and minimal cytoplasm and may be associated with sclerosis. Grossly identified cysts are lined by mitotically inactive polygonal eosinophilic cells with apically oriented nuclei ("hobnailed epithelium"), and the cellularity of their walls may be deceptively low, creating confusion with cystic nephroma in limited biopsy samples. Overall, the appearances are best conceptualized as monophasic spindle-cell synovial sarcoma encircling native renal collecting ducts. True epithelial differentiation yielding a biphasic synovial sarcoma may occur, but this is less common. Immunohistochemically, tumor cells label focally for epithelial markers (EMA more likely than cytokeratin), but many cases are completely negative for all epithelial markers. Many cases have labeled for CD99. The diagnosis can be confirmed in such cases by molecular demonstration of the *SYT-SSX* gene fusion that results from the t(X;18)(p11;q11) that is characteristic of this neoplastic entity. As with renal PNET, renal synovial sarcoma is more aggressive than WT and also may account for some of the adverse prognosis attributed to "adult WT."

WILMS TUMOR (NEPHROBLASTOMA)

Epidemiology

The age-adjusted incidence of pediatric renal tumors in the United States is 7.5 per million children younger than 15 years of age and 6 per million children younger than 19 years of age.[1] Although WT is the most common renal tumor overall, its relative frequency compared with other pediatric renal neoplasms varies according to patient age. Between 0 and 1 month of life, CMN is more common than WT, and after age 14 years RCC surpasses WT as the most prevalent renal cancer.[1,68] In North America the average age of diagnosis for unilateral WT is 42 months for boys and 47 months for girls.[69] Children with clinical malformations, genetic abnormalities, and tumor predisposition syndromes have a significantly earlier median age of diagnosis of WT.[70] For bilateral WT the average age of diagnosis is 30 months for boys and 33 months for girls.[69] The younger age of presentation for bilateral WT is due to genetic predisposition, an observation that provided the basis for Knudson's two-hit model.[71] The reason for the later age of presentation in girls is more elusive. An analysis from the NWTSG revealed that, compared with boys, girls had a relative excess of PLNRs, WT precursor lesions associated with genetic alterations of the Beckwith-Wiedemann syndrome locus at chromosome 11p15.[72] Conversely boys had a relative excess of ILNRs, distinct precursor lesions associated with mutations of the *WT1* gene at chromosome 11p13. ILNR-associated WTs arise at an earlier age than PLNR-associated WTs, partially explaining the gender difference in age distribution. However even in the absence of NRs, girls presented with WTs a few months later, on average, than boys. In North America there is a slight preponderance of WT in girls compared with boys, with a female-to-male ratio of 1.1 to 1.

There also are racial and ethnic differences in the predisposition to WT.[69] Most Caucasian populations have an age-adjusted incidence of six to nine cases per million children annually. Black populations in North America and some parts of Africa exceed 10 cases per million children annually. In Japan, the Philippines, and China, the incidence is fewer than four cases per million children per year. Interestingly, in these East Asian populations, there is an excess of male subjects with WTs, the age at diagnosis is earlier than in North America, and PLNRs are rarely seen.[73] There may also be biologic differences associated with racial differences in WT. A small study of WT in 15 Kenyan children demonstrated differences in molecular signature by imaging mass spectrometry and immunostaining compared with histology and age-matched North American controls. The Kenyan tumors exhibited more aggressive histology and worse outcome, although it is difficult to distinguish truly biologic aggressive disease from inadequate care related to resource limitations.[74]

Several studies have uncovered maternal and paternal environmental associations with WT. Maternal exposures that have been associated with WT include cigarettes, coffee or tea, oral contraceptives, hormonal pregnancy tests, hair-coloring products, hypertension, household pesticide use, and vaginal infections.[75,76] However none of these factors was confirmed by subsequent case-control studies conducted by the NWTSG.[77,78] In a COG study breastfeeding was found to be associated with reduced risk of WT, although the effect was restricted to mothers with less than a college education.[79] On the paternal side the occupations of machinist, welder, and other jobs involving exposure to hydrocarbons or lead were associated with increased risk of WT.[80,81] A subsequent case-control study found an association with the paternal occupations of vehicle mechanics, auto-body repairmen, and welders, although no unifying exposure could be established.[82] A correlation of a low Apgar score (0-5) with a higher risk (46%) of cancer diagnosis was found in a nationwide population-based study in Denmark and Sweden that followed 5,091,188 children from age 0 to 14 years from 1978 to 2006 (excluding children with birth defects). The potential impact of the low Apgar score and cancer diagnosis was largely confined to children diagnosed with cancer before 6 months of age, and the highest risk was observed for the occurrence of WT.[83]

Molecular Biology and Genetics

Retinoblastoma and WT were the original tumors used by Knudson to establish the two-hit hypothesis of oncogenic transformation.[71] Unlike retinoblastoma, in which alterations of a single gene (*Rb*) account for the vast majority of tumors, several genes have been implicated in the genesis of WT, and a sizable proportion of WTs have indeterminate genetic etiology. The genes that are most commonly mutated or epigenetically altered in sporadic WTs are *WT1, IGF2,* β-catenin (*CTNNB1*), *WTX,* and *TP53*. These five genes are discussed in detail in the subsequent sections, whereas other genes and loci implicated in WT are summarized in Table 55-4.

WT1

WT1 was the first gene found to be specifically mutated in WT.[84-86] The gene was originally identified via study of patients with the WAGR syndrome. Children with WAGR suffer from the constellation of *W*T, *a*niridia, *g*enitourinary abnormalities, and mental *r*etardation. Chromosomal analysis of these patients revealed heterozygous constitutional deletions at 11p13. Subsequent investigation of the genes contained within these deletions identified disruption of the *PAX6* gene as the basis of aniridia and *WT1* as the key tumor suppressor. The remaining allele of *WT1* is mutated in the WTs from these patients.

WT1 encodes an approximately 45-kd DNA-binding protein that contains domains rich in glutamine and proline in the amino terminus and four zinc fingers in the carboxy terminus, collectively suggesting that it acts as a transcription factor. The *WT1* gene is quite complex insofar as it encodes numerous distinct isoforms and contains an evolutionarily conserved cryptic splice site that can result in the insertion of three amino acids, lysine, threonine, and serine (KTS), between zinc fingers 3 and 4. Notably distinct functions have been identified for the different KTS isoforms. Patients with Frasier syndrome, characterized by male pseudohermaphroditism, progressive glomerulopathy, and an increased risk of WT, have a congenital donor splice-site mutation in *WT1* that results in loss of the +KTS isoform.[87] Furthermore mice that express only the +KTS or only the −KTS isoform have distinct phenotypes.[88]

Congenital point mutations in *WT1* are also the basis of Denys-Drash syndrome.[89] Patients with this syndrome suffer from renal failure, pseudohermaphroditism, and a susceptibility to WT. Denys-Drash syndrome is caused by missense mutations in *WT1* that disrupt zinc finger binding to DNA. The phenotype of patients with Denys-Drash is quite severe, and evidence suggests that these mutations may lead to a dominant-negative protein that impairs function of the normal protein encoded by the remaining allele. Nonetheless the remaining *WT1* allele is mutated in the WTs that arise in these patients, suggesting that mutation of both alleles is required for tumor formation. Notably whereas mutations in *WT1* are the basis of several syndromes that predispose to the formation of WT, *WT1* is mutated in only 10% to 20% of sporadic tumors.[90] Mouse models have provided insight into the contributions of *WT1* to development and tumor suppression. *WT1* is expressed at high levels in the developing kidney, gonads, spleen, and mesothelium and at lower levels in several other tissues. Mice deficient for *WT1* die midgestation with abnormalities of the metanephric blastema, gonads, mesothelium, heart, and lungs.[91] Cells from the metanephric blastema in these mice undergo apoptosis, and consequently the metanephric kidney never develops. Based on these data it has been postulated that the WT1 protein regulates gene expression pathways required for morphogenesis of the kidney, and that its disruption results in aberrant stimulation of tissue-specific growth. This role in differentiation may also explain why WT is largely a disease of early childhood insofar as kidney morphogenesis is initiated in utero and is completed in early postnatal life. Indeed the level of *WT1* plummets within a few weeks after birth in mice. Whereas $WT1^{-/-}$ mice are not viable, $WT1^{+/-}$ mice live but do not develop WTs. This differs from the human condition in which individuals with germline *WT1* deletions or mutations have a greatly increased risk for developing WT compared with the general population.

β-catenin (CTNNB1)

The Wnt signaling pathway regulates the cellular processes of proliferation, differentiation, motility, and

TABLE 55-4 Genes and Loci Associated with Wilms Tumor

Locus	Gene	Gene Function	Comments	Key References
11p13	*WT1*	Transcription factor	WAGR, Denys-Drash, and Frasier syndromes associated with WT predisposition; somatic mutations in 10% to 20% of WT	84-86, 90
11p15	*WT2 (IGF2/ H19)*	Insulin-like growth factor pathway	Beckwith-Wiedemann syndrome associated with WT predisposition; somatic genetic or epigenetic alterations seen in 70% of WT	113-115
Xq11	*WTX (AMER1/ FAM123B)*	Wnt signaling pathway	Osteopathia striata congenita with cranial sclerosis syndrome has not been associated with WT predisposition but somatic mutations seen in 20% to 30% of WT	97-99
3p21	*CTNNB1 (β-catenin)*	Wnt signaling pathway	Somatic mutations seen in 15% of WT; strong correlation with *WT1* mutations	93, 94
17q12-q21	*FWT1*	Unknown	Locus associated with familial WT; gene not identified	305, 306
19q13	*FWT2*	Unknown	Locus associated with familial WT; gene not identified	307
17p13	*TP53*	Cell cycle checkpoint and apoptosis	Li-Fraumeni syndrome associated with WT predisposition; somatic mutations seen in 75% of anaplastic WT but uncommon in favorable-histology WT	11, 12, 120
13q12	*BRCA2 (FANCD1)*	DNA repair	Fanconi anemia; biallelic mutations associated with WT predisposition	308, 309
16p12	*PALB2 (FANCN)*	DNA repair	Fanconi anemia; associated with WT predisposition	310
15q26	*BLM*	DNA helicase	Bloom syndrome; associated with WT predisposition	311-313
15q15	*BUB1B*	Mitotic spindle checkpoint	Mosaic variegated aneuploidy; associated with WT predisposition	311, 314
Xq26	*GPC3*	Wnt signaling pathway	Simpson-Golabi-Behmel syndrome; associated with WT predisposition	311, 315-318
2q37	*DIS3L2*	Micro-RNA processsing	Perlman syndrome; associated with WT predisposition	319
7p14-15	*POU6F2*	Transcription factor	None	320, 321
1q25-q32	*HRPT 2* (parafibromin)	RNA processing; histone modification	Hyperparathyroidism-jaw tumor	322
6q21	*HACE1*	Ubiquitin ligase	None	323, 324
2p24	*MYCN*	Transcription factor	Somatic gene amplification seen in 5% to 10% of WT	325
4q31	*FBXW7*	Ubiquitin ligase	Somatic mutations seen in 4% of WT; germline mutation described	326

WAGR, Constellation of *W*ilms tumor, *a*niridia, *g*enitourinary abnormalities, and mental *r*etardation; *WT,* Wilms tumor.

survival. Central to the pathway is the transcriptional activator β-catenin, which is actively degraded in the absence of Wnt signaling.[92] Activating mutations in the *β-catenin (CTNNB1)* gene occur in approximately 15% of WTs.[93,94] Interestingly mutations in *β-catenin* occur predominantly in tumors in which *WT1* is also mutated, suggesting that these two events cooperate in the genesis of WT.[94,95] In the developing kidney *Wnt4* is an inducer of the mesenchymal to epithelial transition that underlies normal nephron development; disruption of normal renal development may be the means by which *β-catenin* mutation contributes to the formation of WT.[96]

WTX (AMER1/FAM123B)

WTX was discovered by an array comparative genomic hybridization screen that identified deletions of the Xq11.1 locus in male patients with WT. Further investigation found deletions and mutations in girls. Intriguingly *WTX* is inactivated by a single hit affecting either the sole *WTX* copy in male subjects or the copy located on the active X chromosome in female subjects.[97] According to the initial report, *WTX* was deleted or mutated in approximately one third of WTs, although other groups have reported a lower mutation frequency.[97-99] Germline *WTX* mutations have been observed in individuals with osteopathia striata congenita with cranial sclerosis, a rare slerosing bone dyspasia.[100] Individuals with osteopathia striata congenita with cranial sclerosis do not have increased risk for WT or other cancers, but NRs have been observed in one individual with a germline *WTX* mutation.[101]

WTX is alternatively spliced to encode two isoforms of a protein with disparate functions.[100] The short isoform of the protein is nuclear and forms a complex with β-catenin, AXIN1, APC, and β-TrCP2, ultimately promoting ubiquitination and degradation of β-catenin, thereby acting as a negative regulator of the WNT signaling pathway.[102] The full-length WTX protein binds to the adenomatous polyposis coli protein and regulates its distribution between microtubules and the plasma membrane.[103] WTX also interacts with WT1 protein and enhances its function as a transcriptional activator.[104] It was recently shown to bind p53 and modulate p53 function through its activator CBP/p300.[105]

Although *WT1* and *β-catenin* mutations are highly concordant, there is no clear association between *WT1* and *WTX* mutations.[97,98] This suggests that *WTX* and *β-catenin* mutations are not functionally equivalent even though both proteins reside within the WNT pathway.

IGF2

Cytogenetic analyses have long suggested the presence of an additional WT gene at 11p15 distinct from the *WT1* locus at 11p13.[106] Loss of heterozygosity (LOH) at 11p15 occurs in some cases of sporadic WT. Additionally, this locus is linked to Beckwith-Wiedemann syndrome (BWS), an overgrowth disorder associated with macroglossia, umbilical hernia, gigantism, neonatal hypoglycemia, and predisposition to WT and other cancers. BWS arises from alterations in several different genomically imprinted genes at the 11p15 locus.[107] Genomic imprinting is the preferential expression of a gene from either the maternal or paternal allele. The molecular basis of genomic imprinting is epigenetic modification, most notably DNA methylation. The 11p15 locus has two imprinting domains (Fig. 55-13). The telomeric domain (domain 1) includes the genes *insulin-like growth factor 2 (IGF2)* and *H19*. *IGF2* encodes a growth factor expressed at high levels in the developing kidney and WT.[108,109] *H19* encodes a biologically active untranslated RNA that may function as a tumor suppressor.[110] In normal cells these genes are oppositely expressed such that *IGF2* is expressed only from the paternal allele and *H19* is expressed only from the maternal allele. The centromeric imprinting domain (domain 2) contains several imprinted genes, including *KCNQ1* (*KvLQT1*), *KCNQ1OT1 (LIT1)*, and *CDKN1C* (*p57*^{KIP2}). *KCNQ1* encodes a subunit of a voltage-gated potassium channel that is implicated in several cardiac arrhythmia syndromes, including long-QT syndrome 1. *KCNQ1OT1* encodes a noncoding RNA with antisense transcription of *KCNQ1*. *CDKN1C* encodes a member of the cyclin-dependent kinase inhibitor family of proteins that negatively regulates cell proliferation and is a tumor suppressor. Molecular subgroups of BWS include those with (1) loss of methylation in domain 2, which is associated with decreased expression of *CDKN1C* (~50%); (2) duplication of domains 1 and 2 of the paternal allele with no maternal contribution (uniparental isodisomy) (~20%); (3) mutation of CDKN1C (~10%); (4) gain of methylation of domain 1, resulting in increased IGF2 expression and decreased H19 expression (~2% to 7%); 5) small duplications or chromosome rearrangements (<2%); and (5) unknown genetic etiology (~13% to 15%).[107] Interestingly, the Silver-Russell syndrome, associated with growth retardation, is caused by loss of methylation at domain 1 and maternal 11p15 duplication (i.e., the opposite of BWS).[111,112]

In the past decade correlations between BWS genotypes and cancer predisposition have emerged. Uniparental isodisomy and gain of methylation at domain 1 carry the highest risk of WT. Loss of methylation at domain 2 is associated with omphalocele, macrosomia, and a distinct lack of WT, although these individuals develop other tumor types.[113-115] A common thread in the patients most susceptible to WT is increased expression of *IGF2*.

Wilms Tumor Subsets Defined by Genetic and Epigenetic Features

A traditional model of WT development purports that WTs fall into two discrete subtypes: type I and type II.[72,116] Type I WT is caused by *WT1* mutation, resulting in intralobar NRs, which then accumulate second hits

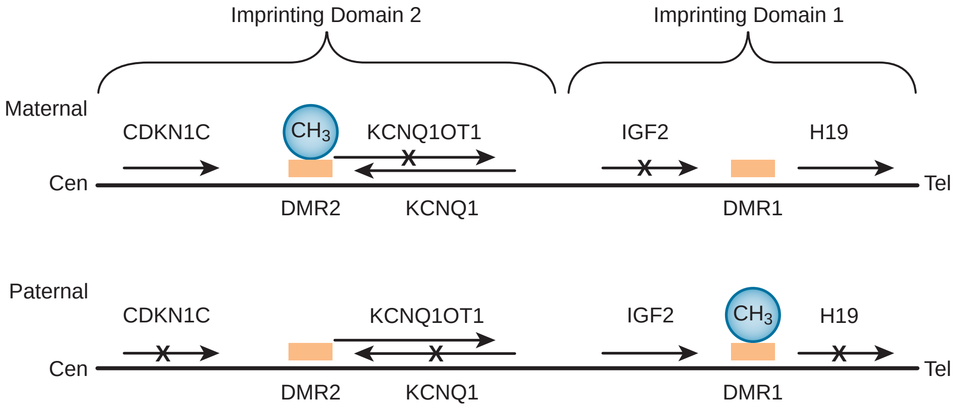

Figure 55-13 The Beckwith-Wiedemann syndrome locus. The chromosome 11p15.5 locus contains several imprinted genes clustered in two imprinting domains: centromeric *(cen)* and telomeric *(tel)*. Each domain has a differentially methylated region *(DMR)* that controls expression of surrounding genes. In normal individuals the DMR of domain 1 is methylated in the paternal allele, resulting in expression of *IGF2* and silencing of *H19*. In normal individuals the DMR of domain 2 is methylated in the maternal allele, resulting in expression of *CDKN1C (p57)* and *KCNQ1* and silencing of *KCNQ1OT(LIT1)*. Beckwith-Wiedemann syndrome can arise from decreased methylation of domain 2, increased methylation of domain 1, duplication of the paternal 11p15 allele with no contribution of the maternal allele (uniparental isodisomy), or small deletions or rearrangements. Increased methylation of domain 1 and uniparental isodisomy carry the greatest risk of Wilms tumor.

such as Wnt activating mutations (β-catenin or WTX mutations). Type II WT is caused by genetic or epigenetic changes in the 11p15 locus that result in IGF2 overexpression, perilobar NRs, and presumably other second-hit genetic changes that lead to WT. Comprehensive mutation analyses of WT1, β-catenin, WTX, and the 11p15 locus in WT samples indicate that whereas some tumors fit the classic paradigm, other tumors have evidence of both *IGF2* overexpression and *WT1* mutation. Indeed transgenic mice with *Igf2* overexpression and *Wt1* deletion developed WT, whereas neither genetic abnormality alone was sufficient to cause WT.[117] Other WTs lack evidence of either *IGF2* or *WT1* alteration. The requirement for coexisting mutations likely depends on the developmental stage of the cell of origin of a particular tumor.[118]

TP53

Constitutional mutations of the *TP53* gene are responsible for Li-Fraumeni syndrome (LFS), which predisposes carriers to cancer.[119] *TP53*, one of the most commonly mutated genes in human cancer, encodes a transcription factor that is a master regulator of cell cycle arrest, apoptosis, and DNA repair in response to a variety of stimuli. Although WT is not a defining criterion for LFS, several LFS families with WT have been identified.[120] It is important to note that *TP53* mutations are associated with the anaplastic histology subtype of WT; approximately 75% of anaplastic WTs have detectable *TP53* mutations, whereas *TP53* mutations are uncommon in favorable histology tumors.[11,121,122] Several lines of evidence suggest that anaplastic WT arises from the acquisition of a *TP53* mutation in a favorable histology WT. First, patients with bilateral WT often have discordant histologies between contralateral tumors.[15] Second, some WTs have favorable histologic features at diagnosis but are found to have anaplastic histology at relapse.[121] Finally, microdissected WTs were found to have *TP53* mutations restricted to areas of anaplasia within the tumor tissue.[12]

Clinical Presentation and Diagnostic Evaluation

The most common presenting signs and symptoms of WT are abdominal mass (75%), abdominal pain (28%), hypertension (26%), gross hematuria (18%), microscopic hematuria (24%), and fever (22%).[123] The hypertension, which can be severe, may be due to ectopic renin production by the tumor, compression of the renal artery by the tumor with resulting physiologic renin production, or ectopic adrenocorticotropic hormone production. An analysis of 31 patients with WT with hypertension at diagnosis found increased plasma renin levels in 81% of patients.[124] Some patients have persistent hypertension after the tumor has been removed, suggesting underlying renal pathology. There are no tumor markers pathognomic for WT, although associated laboratory findings include hematuria and anemia. An association between WT and acquired von Willebrand disease has been described.[125]

WT can spread locally or hematogenously. Locally the tumor has the potential to spread into structures surrounding the kidney and can occasionally invade other organs such as the liver. If the tumor ruptures, peritoneal tumor deposits can be detected. WT also spreads to lymph nodes near the renal hilum and in the paraaortic chain. Between 6% and 8% of WTs spread through the renal vein and form a tumor thrombus in the inferior vena cava, which can propagate into the heart.[126,127] The most common sites of distant metastasis are the lung and liver. There are reports of WT spread to brain or bone, but this is very uncommon. About 7% of patients have synchronous or metachronous bilateral tumors, and 10% have unilateral multifocal tumors.[69]

Radiologic evaluation of WT focuses on the identification of local and distant sites of spread. A computed tomography (CT) scan of the abdomen and pelvis is recommended to visualize the primary tumor, the contralateral kidney, lymph nodes, and intraabdominal or pelvic tumor deposits. CT also provides information valuable to surgical planning. Assessment of the diagnostic performance of CT in identifying the presence or absence of preoperative rupture found moderate specificity but relatively low sensitivity when CT findings were compared to operative notes or pathologic examination. The single best indicator of rupture was the finding of ascites beyond the cul-de-sac, followed by perinephric fat stranding and retroperitoneal fluid.[128] Doppler ultrasound has historically been used as a complementary test to evaluate for tumor thrombus in the renal vein and inferior vena cava. The detection of tumor thrombus by CT versus ultrasound was compared in a study population drawn from the first 1015 patients enrolled on the COG AREN03B2 Renal Tumor Biology and Risk Classification study. CT scans from 62 children with and 111 children without tumor thrombus identified at nephrectomy were reviewed. Comparable sensitivity and specificity of CT and ultrasound were found for detection of cavoatrial thrombus. These findings suggest that CT can adequately identify tumor thrombus that will affect surgical approach and that Doppler ultrasound evaluation is not a diagnostic requirement.[129] CT imaging can also aid in surgical planning by allowing an estimation of tumor weight before surgery.[130,131] In the COG AREN03B2 risk-stratification process, tumors less than 550 gm are considered for treatment with observation only, and preoperative weight estimation can be used in determining the appropriateness of central line placement at time of nephrectomy. On the other end of the spectrum, tumors greater than 1000 gm have also been associated with an increased risk of intraoperative spill; therefore estimation of larger size can also be a factor in surgical planning.[132]

Chest x-rays have historically been used to assess patients for lung metastases, but CT scans are more sensitive in detecting nodules or effusions.[133,134] On NWTS-5, 129 patients had lung lesions detected on CT scan but not chest x-ray. Forty-two of these patients with "CT-only" nodules had lung biopsies, and tumor was confirmed in 31 patients (73.8%).[135] Retrospective studies of the prognostic significance of CT-only lung nodules have yielded conflicting results.[133,136-139] The largest analysis to date included 186 patients with CT-only nodules from

NWTS-4 and -5. These patients were treated heterogeneously (+/– doxorubicin, +/– lung radiation) because the treatment decisions were left to the discretion of the local physicians. Outcome analysis found that patients with CT-only nodules who were treated with doxorubicin had superior relapse-free survival compared with patients who did not receive doxorubicin, but the study found no impact on overall survival. The use of lung radiation did not have a significant effect on outcome.[140,141] Based on these findings, the first generation of COG renal tumor studies recommended CT scans, but not chest x-rays, for the diagnostic staging evaluation for WT. Lung nodules are considered to contain tumor unless biopsy proves otherwise.

Bone scan and brain magnetic resonance imaging are not routinely recommended in the evaluation of patients with newly diagnosed WT. Fluorodeoxyglucose (FDG) positron emission tomography (PET) scanning is not a routine part of the WT workup. Initial experience with PET scans indicates that most WTs are FDG avid.[142,143] Correlations of PET avidity and measures of standardized uptake value with histology and treatment response have been reported in small patient series. These studies suggest that FDG PET may have value in assessing response to chemotherapy as well as a role in identifying tumor viability in lesions with no radiologic evidence of change.[144-146]

Treatment

The treatment approach to WT has evolved along two distinct pathways. The NWTSG, which became the Renal Tumor Committee of COG in 2002, advocates the upfront nephrectomy approach whenever surgically and medically feasible, followed by chemotherapy. This approach provides for accurate histologic diagnosis and staging information. In contrast, SIOP uses preoperative chemotherapy, which shrinks the tumor, thereby reducing the risk of surgical complications such as intraoperative tumor spillage. It is difficult to compare the two approaches side by side because of differences in the staging systems and treatment plans, but both approaches produce excellent outcomes. Regardless of the timing of initial surgery, the three pillars of WT treatment are surgery, chemotherapy, and radiation therapy.

Surgery

In the SIOP treatment protocols, patients 6 months of age or older receive chemotherapy before surgery unless there is evidence of tumor rupture, in which case they undergo immediate nephrectomy. Open or needle biopsy is not routinely performed. Infants younger than 6 months old are treated with upfront nephrectomy because non-Wilms renal tumors, such as mesoblastic nephroma or malignant rhabdoid tumor, are prevalent in this age group.

In the COG treatment protocols, all patients are considered candidates for immediate surgery, although there are several indications to give preoperative chemotherapy: (1) bilateral WT; (2) tumor thrombus in the inferior vena cava above the level of the hepatic veins; (3) tumors that invade adjacent organs such that resection of the tumor would involve resection of the other structures (except the adrenal gland); (4) tumors that, in the surgeon's judgment, would result in significant morbidity or mortality if resected before chemotherapy; and (5) respiratory distress resulting from extensive pulmonary metastatic disease. If preoperative chemotherapy is given, it is recommended not to delay definitive surgery beyond week 12 of treatment.

A generous transabdominal, transperitoneal, or thoracoabdominal incision is recommended for adequate exposure. An increased rate of rupture and complication is associated with a midline laparotomy.[147] Complete exploration of the abdomen should be performed, followed by a radical nephrectomy, dividing the ureter as distally as possible. Routine exploration of the contralateral kidney is not recommended if imaging is satisfactory and does not suggest a bilateral process because the chance of detecting a contralateral kidney tumor during surgery that is undetected with modern imaging techniques is less than 1%, and the outcome of these patients is excellent.[148] An important component of WT surgery is lymph node sampling, even if the nodes appear normal. NWTS-4 showed that patients with positive lymph nodes had better outcomes than patients whose lymph nodes were not sampled, indicating that some patients who did not undergo lymph node sampling were understaged and undertreated.[149] Another important facet of surgery is to remove the tumor en bloc, avoiding tumor spillage. Intraoperative spillage was shown to increase the risk of tumor recurrence.[149] In a review of the first 2000 patients enrolled on COG Biology and Risk Stratification study AREN03B2, an intraoperative rupture rate of 9.7% was found in 1131 primary nephrectomies for unilateral WT. Risk factors for intraoperative spill were diameter (>12 cm) and laterality (right).[150]

Surgical resection or biopsy of lung nodules plays an important role in the diagnosis of metastatic WT. Current COG renal tumor studies consider circular lung nodules, regardless of size, to be metastatic disease unless proven benign by biopsy. The resection of lung metastases may also provide a therapeutic benefit. In the SIOP protocols, patients whose lung nodules are resected completely do not receive pulmonary radiation therapy (XRT). The COG AREN0533 study tested a new strategy for favorable-histology WT with lung metastases. Lung nodules were assessed after 6 weeks of chemotherapy and XRT omitted for patients with a complete response. With this approach it is appropriate not to resect all lung nodules upfront to assess chemosensitivity.

Radiation Therapy

Radiation therapy is a mainstay of WT treatment. Initially used in all patients with WT, successive studies from the NWTSG and SIOP demonstrated that only patients with stage III or IV disease require radiation therapy (Table 55-5). Among these patients radiation doses have been reduced over time, thereby decreasing the potential for late adverse effects.

The radiation guidelines for favorable-histology WT that were used in NWTS-5 are commonly applied as standard practice in North America. Patients with positive lymph nodes, positive tumor margins after surgery,

TABLE 55-5 Key Findings of National Wilms Tumor and SIOP Studies

NWTS Study	Key Findings	SIOP Study	Key Findings
NWTS-1 (1969-1973)	Group I: XRT not beneficial for patients <2 years of age treated with AMD Group II/III: VCR/AMD superior to either agent alone; anaplastic histology strongly predictive of adverse outcome	SIOP 1 (1971-1974)	Preoperative XRT reduces the number of tumor ruptures and produces more low-stage tumors
NWTS-2 (1974-1978)	Group I: reduction of chemotherapy duration from 15 to 6 months did not adversely affect RFS; XRT not needed for this group Group II: inferior outcome for those with lymph node involvement Groups II-IV: addition of DOX to VCR/AMD improved outcome	SIOP 2 (1974-1976)	9 months of VCR/AMD equivalent to 15 months Reduction of tumor ruptures in preoperative treatment group confirmed
NWTS-3 (1979-1986)	Stage I FH: RFS similar whether duration of VCR/AMD was 10 or 26 weeks Stage II FH: Addition of DOX to VCR/AMD did not improve RFS; XRT not necessary Stage III FH: • Without DOX, 20 Gy flank XRT superior to 10 Gy • Addition of DOX to 10 Gy flank XRT improved RFS • Addition of DOX to 20 Gy flank XRT did not improve RFS Stage IV FH: Addition of CYCLO did not improve RFS Stage II to IV diffuse anaplasia: Addition of CYCLO appeared to improve RFS	SIOP 5 (1977-1979) SIOP 6 (1980-1987)	Preoperative chemotherapy equivalent to XRT in preventing tumor ruptures Stage I: 17 weeks VCR/AMD equal to 38 weeks Stage IIN0: Withholding XRT triggered stopping rule because of abdominal relapses; however, DFS and OS were not affected by withholding XRT Stage IIN+/III: DOX improved DFS but not OS
NWTS-4 (1986-1994)	Stage I to IV FH: No difference in RFS when AMD was given as a single dose rather than as 5 doses; toxicity profile and cost better with single dose Stage III to IV FH: No difference in RFS when DOX given as a single dose rather than as 3 doses; toxicity profile and cost better with single dose Stage II to IV FH: No difference in RFS between 6 and 15 months of therapy Stage II to IV diffuse anaplasia: Improved RFS with addition of CYCLO confirmed	SIOP 9 (1987-1991)	4 weeks of preoperative VCR/AMD is equivalent to 8 weeks in terms of % of stage I tumors, EFS, and OS
NWTS-5 (1995-2002)	Stage I FH, age <2 years, tumor <550 gm: Without chemotherapy, 2-year RFS rate was only 86% but OS was 100% Stage I to IV FH: LOH at 1p and 16q predict decreased RFS and OS Stage I anaplasia: RFS and OS inferior to stage I FH Stage II-IV diffuse anaplasia: Best reported outcomes to date using VCR/DOX/CYCLO/ETOP	SIOP 93-01 (1993-1999)	Patients with stage I WT do just as well with 4 weeks of postoperative VCR/AMD as with 18 weeks Postchemotherapy histology predictive of relapse: complete necrosis = low risk; blastemal predominance = high risk

or tumor spillage receive 10.8 Gy to the flank. Patients with diffuse tumor spillage or peritoneal seeding receive 10.8 Gy to the whole abdomen. Sites of gross residual disease after surgery receive a boost of 10.8 Gy. Early reports from the NWTSG demonstrated that XRT delay beyond 9 days from surgery was an adverse prognostic factor.[151,152] NWTSG studies recommended that radiation commence by day 9 after surgery. However a retrospective analysis of NWTS-3 and -4 did not detect a difference in local recurrence rate between patients who received radiation within 9 days and patients whose radiation was delayed beyond day 9, although very few patients had XRT delayed much beyond day 10.[153] To allow for real time central review and risk stratification, COG renal tumor therapeutic protocols allow up to 14 days from surgery to initiation of abdominal or flank radiation. Patients whose tumors are initially unresectable have radiation therapy delayed until after definitive surgery.

The local radiation doses that the SIOP treatment protocols use are higher than those in COG studies. Patients with stage III intermediate-risk histology receive 14.4 Gy to the abdomen or flank rather than 10.8 Gy. Patients with stage II or III high-risk histology receive 25.2 Gy.

The radiation guidelines for patients with distant metastatic disease are evolving. The most common metastatic site is the lung. In the NWTSG studies all patients with lung metastases received whole lung radiation to a dose of 12 Gy at the beginning of treatment, yielding 16-year relapse-free survival rates of 80%.[154] In SIOP studies patients whose lung nodules resolve with chemotherapy and surgery did not receive lung XRT. A number of studies using this approach have showed varied outcome.

With this approach the 4-year survival rate was 83%.[155] However the United Kingdom Wilms Tumor Study used the SIOP approach and observed a 6-year survival rate of only 65%.[156] In the SIOP 93-01 protocol, patients were treated with 6 weeks of three-drug (vincristine/dactinomycin/doxorubicin) preoperative chemotherapy. Patients in complete remission (CR) after 6 weeks of chemotherapy +/– surgical metastasectomy did not receive pulmonary radiation and continued with three-drug therapy. Patients without CR at 6 weeks received intensified chemotherapy with etoposide/carboplatin and ifosfamide/doxorubicin. If after 9 weeks of this therapy, CR was obtained, no pulmonary radiation was given. If CR was not obtained, patients received 15 Gy of lung radiation with a boost to residual disease. In the study 84% of patients were in CR after the initial 6 weeks of therapy, 17% requiring metastectomy. Only 14% of patients received radiation as front-line therapy. Patients in CR after chemotherapy only or chemotherapy and metastectomy had good overall survival rates (88% and 92%), whereas patients with residual pulmonary metastatic disease had a significantly lower overall survival rate of 48%. This disparity may relate to differences in patient populations and treatment, but it raises the question of whether more stringent selection criteria should be used for withholding lung XRT.

The COG AREN0533 Higher Risk Favorable Histology Wilms Tumor study also stratified therapy according to the lung nodule response after 6 weeks of three-drug chemotherapy. The study asked whether XRT can be omitted without compromising event-free survival for patients whose lung nodules disappear after 6 weeks of chemotherapy and whether outcomes can be improved by intensifying chemotherapy therapy for patients whose lung nodules do not resolve. Patients without pulmonary complete response received 1200 cGy (1050 cGy for ages younger than 12 months) of pulmonary XRT and an intensified chemotherapy with cyclophosphamide/etoposide added to the three-drug therapy. That study closed in 2013 after reaching accrual of 395 patients, and results have not yet been published.

Chemotherapy

In the mid-1950s Farber and colleagues pioneered the use of dactinomycin as an adjunct to surgery and radiation therapy for the treatment of WT. With the introduction of dactinomycin, unprecedented survival rates were observed, particularly in patients with metastatic disease.[157] In the early 1960s the Southwest Oncology Group found that vincristine produced regression of metastatic WT and that the response to vincristine plus XRT was similar to that reported for dactinomycin.[158] In 1969 the first National Wilms Tumor Study (NWTS-1) found the combination of vincristine and dactinomycin to be superior to either agent alone for groups II and III tumors.[159] Since then vincristine/dactinomycin has been the backbone of WT therapy worldwide, although subsets of patients with stage I disease fare well with vincristine alone or even surgery only, as discussed later. In the early 1970s the third stalwart of WT chemotherapy regimens, doxorubicin, was introduced. NWTS-2 demonstrated the benefit of doxorubicin for patients with groups II to IV disease, and NWTS-3 showed that radiation doses can be reduced when doxorubicin is used.[160,161] NWTS-4 refined how dactinomycin and doxorubicin are given. Both agents were as effective when delivered as a single dose rather than as separate doses over 5 (dactinomycin) or 3 (doxorubicin) days.[162] Not only was this "pulse-intensive" dosing more convenient and cost-effective, but it also was associated with less hematologic toxicity.[163,164] The key findings of the NWTSG studies are summarized in Table 55-5.

By the end of NWTS-4 the survival rate for patients with favorable histology WT was approximately 90%. Given this success the priority for NWTS-5 was to identify novel prognostic markers to help stratify patients into risk-appropriate treatment groups. Pilot data from NWTS-3 and -4 showed that LOH at chromosomes 1p and 16q was associated with adverse outcome in patients with WT.[165] Following this lead NWTS-5 prospectively evaluated the prognostic significance of LOH in more than 2000 patients.[166] There was no significant association between LOH and outcome in patients with anaplastic WT, CCSK, or MRT. However LOH at 1p and 16q was associated with increased risk of relapse and death in patients with favorable-histology WT, with the greatest effect seen in tumors with LOH at both loci (Table 55-6).

A second objective of NWTS-5 was to determine whether therapy can be reduced in selected populations of patients with truly outstanding outcomes. Earlier studies suggested that young patients with small stage I tumors with favorable histology have excellent outcomes, so NWTS-5 asked if these patients could be treated with

surgery alone, without adjuvant chemotherapy and radiation therapy.[167] Among 75 patients treated with surgery only, eight patients relapsed and three patients developed metachronous tumors in the contralateral kidney.[168] The 2-year disease-free survival rate was only 86%, which triggered a stopping rule, and the study was discontinued. However 74 of the 75 patients survived, suggesting that the nephrectomy-only approach should be revisited. Although the standard treatment for stage I favorable-histology WT in North America is 18 weeks of vincristine and dactinomycin, the United Kingdom WT group treated with 10 weeks of vincristine only and the SIOP 93-01 study demonstrated that 4 weeks of postoperative treatment is equivalent to 18 weeks.[169,170] The treatment regimens from NWTS-5 are summarized in Table 55-7, and the corresponding outcomes are summarized in Table 55-8.

With the foundation of the findings from the NWTS studies, the first COG renal tumor studies (opened 2006) aimed to further refine the treatment of favorable-histology WT. For entry into any COG Renal Tumor Therapeutic study, patients first had to enroll in the COG Renal Tumor Biology and Risk Stratification study AREN03B2, which continued the NWTSG tradition of central pathology and surgery review and tumor banking. More than 4000 patients enrolled in the first 6 years of the study, with a steady accrual of 600 patients annually. Submission of pathology slides, radiology images, operative reports, and tumor and blood samples for analysis was required within 7 days of surgery to meet enrollment deadlines stipulated by the therapeutic studies. Central pathology review for histology and stage, radiology review for presence of bilateral lesions and pulmonary metastases, and surgical review for operative stage were completed electronically by a panel of expert reviewers. An Initial Risk Assignment was made by the study chairs on the basis of the multidisciplinary central reviews. Final Risk Assignments included LOH status of 1p and 16q for patients with favorable-histology WT, and response of pulmonary metastases for patients with stage IV favorable-histology WT. Real-time central review was shown to be feasible, with a median time to Initial Risk Assignment of 8 days from initial surgical procedure.

The AREN0532 study for the treatment of Very Low and Standard Risk Favorable-Histology WT reassessed the feasibility of surgery without adjuvant therapy for patients younger than 2 years old with stage I favorable-histology WTs less than 550 grams. Participation in this study arm required a real-time central review with verification of lymph node sampling confirmed negative for tumor, and the patient could not have an underlying predisposition syndrome, contralateral rests, or multifocal tumors. The study completed accrual of 116 patients with very low-risk disease in August 2013, and outcome data are pending. AREN0532 also assessed the benefit of therapy augmentation for patients with stage I and II favorable-histology WT with LOH at 1p and 16q. Instead of receiving the standard therapy with vincristine and dactinomycin, patients with LOH receive vincristine, dactinomycin, and doxorubicin. Likewise, the AREN0533 study (higher-risk favorable-histology WT) augmented therapy for patients with stage III and IV favorable-histology WT with LOH at 1p and 16q. Instead of receiving vincristine, dactinomycin, and doxorubicin, these patients received a new regimen that added four cycles of cyclophosphamide and etoposide to the standard treatment. AREN0533 also introduced a new approach to patients with lung metastases. Patients whose lung nodules responded completely after 6 weeks of vincristine, dactinomycin, and doxorubicin chemotherapy did not receive lung radiation therapy (see previous section on radiation therapy). By contrast, patients whose lung nodules did respond completely received radiation therapy and augmented chemotherapy with vincristine, dactinomycin, doxorubicin, cyclophosphamide, and etoposide.

The SIOP 2001 study aimed to evaluate whether doxorubicin is necessary for patients with stage II and III intermediate-risk tumors; patients were randomized to receive vincristine and dactinomycin with or without doxorubicin. Preliminary analysis showed equivalent 5-year overall survival of 96% in both treatment groups.[171] The study also adjusted chemotherapy according to

TABLE 55-8 NWTS-5: Treatment Results

Stage	4-Year Relapse-Free Survival Rate (%)	4-Year Overall Survival Rate (%)

histologic response to preoperative treatment. Patients with stage I blastemal predominance after 4 weeks of preoperative chemotherapy received a regimen containing doxorubicin instead of just vincristine and dactinomycin. Patients with stage II and III blastemal predominance received a regimen of alternating cyclophosphamide and doxorubicin with carboplatin and etoposide.

Anaplastic Wilms Tumor

In 1978 Beckwith and Palmer published a detailed histopathologic review of the patients entered in the first NWTSG.[172] Approximately 6% of the WT specimens contained anaplasia, as defined in the pathology section of this chapter. The presence of anaplasia was prognostically significant; 11 of 25 (44%) patients with anaplasia died as a result of tumor, whereas only 26 of 364 (7.1%) patients without anaplasia died as a result of tumor. Subsequent National Wilms Tumor Studies, as well as SIOP and the United Kingdom Wilms Tumor Study, confirmed the adverse prognostic significance of anaplastic histology.[156,173,174]

The first NWTSG trial to stratify patients with anaplastic WT into a distinct treatment group was NWTS-3. In this study and in NWTS-4, patients received 15 months of vincristine, dactinomycin, and doxorubicin and were randomized to receive or not receive cyclophosphamide. Patients with stages II through IV diffuse anaplastic WT had a 4-year relapse-free survival rate estimate of 27.2% when treated without cyclophosphamide, compared with 54.8% when treated with cyclophosphamide ($P = .02$).[175] Patients with all stages of focal anaplastic histology and stage I diffuse anaplastic histology had excellent outcomes regardless of treatment regimen.[161,162]

On the basis of these results, cyclophosphamide was incorporated into the treatment plan of NWTS-5 for patients with stages II and IV diffuse anaplastic WT. Patients received a regimen consisting of vincristine, doxorubicin, and cyclophosphamide alternating with cyclophosphamide and etoposide for 24 weeks of treatment and flank radiation therapy to a dose of 10.8 Gy.[15] With this regimen the 4-year relapse-free survival rate and overall survival rate compared favorably with historic data from NWTS-3 and -4 (see Table 55-8). Patients with stage I diffuse anaplastic histology were treated with vincristine and dactinomycin according to the regimen used for favorable-histology WT. With this approach the 4-year event-free survival was only 68.4%, significantly worse than that seen for stage I favorable-histology tumors.[15] Patients with stage II through IV focal anaplastic WT were treated with vincristine, doxorubicin, dactinomycin, and radiation therapy and had outcomes intermediate between favorable histology and diffuse anaplasia (see Table 55-8).

AREN0321, the COG study for high-risk renal tumors, sought to build on the NWTS-5 experience by adding carboplatin to the treatment regimen for diffuse anaplastic WT. Patients were scheduled to receive 31 weeks of alternating vincristine, doxorubicin, and cyclophosphamide, and cyclophosphamide, carboplatin, and etoposide with flank radiation therapy. Because of the poorer-than-expected outcomes for stage I anaplastic WT, the AREN0321 study treated such patients with vincristine, dactinomycin, doxorubicin, and radiation therapy instead of just vincristine and dactinomycin. Patients with stage IV diffuse anaplastic WT had a 4-year relapse-free survival rate estimate of only 33% in NWTS-5. For this group the priority was to identify new chemotherapy combinations. The AREN0321 study included a phase 2 "window" study to evaluate the antitumor activity of vincristine and irinotecan. This combination was selected on the basis of preclinical and clinical data showing activity of the camptothecins (topotecan and irinotecan) against WT.[176] The study was opened in 2006 and permanently closed to accrual in 2013. Outcome results are pending.

Bilateral Wilms Tumor

Between 4% and 6% of patients with WT have tumor involvement of both kidneys at initial presentation (synchronous bilateral WT).[69] These patients pose a dual challenge, with the need to eradicate the tumor cells while preserving renal function. Although renal failure occurs in fewer than 1% of patients with unilateral WT, the long-term incidence of renal failure in patients with bilateral WT has been reported to range from 11% to 20%.[177] Historically synchronous bilateral WT was managed with surgical resection followed by chemotherapy. Typically a unilateral nephrectomy of the more involved kidney was performed with biopsy or partial nephrectomy of the contralateral kidney, followed by adjuvant therapy. With the recognition that chemotherapy could decrease tumor volume and facilitate partial nephrectomy, preoperative chemotherapy has become the standard approach to treatment. Data from the NWTSG showed no difference in outcome whether the tumor was resected at the time of diagnosis or after preoperative chemotherapy.[178-180] Despite the effectiveness of preoperative chemotherapy, approximately 60% of patients continue to undergo nephrectomy of at least one kidney. In NWTS-4 only 19% of patients underwent bilateral nephron-sparing procedures, but more recent data from single-institution series suggest that more patients are candidates for bilateral partial nephrectomies.[181-183] NWTS data also showed that children with bilateral WT or WT and contralateral NRs who had complete radiologic resolution lesions in a kidney after initial treatment did well without surgical intervention to that kidney.[184] An aim of the current COG AREN0534 study for bilateral WT is to decrease the percentage of patients who require nephrectomy.

Chemotherapy regimens for bilateral WT use the same agents as for unilateral WT. In the NWTSG and SIOP studies, patients started treatment with vincristine and dactinomycin therapy and doxorubicin was reserved for patients known to have distant metastatic disease, locally advanced disease, or poor response to therapy. With this treatment approach long-term survival rates for patients with synchronous bilateral WTs were approximately 70% to 80%.[178-180] The COG AREN0534 study for bilateral WT treats all patients with vincristine, dactinomycin, and doxorubicin before surgery to promote improved local control. Given the high likelihood of bilateral renal lesions representing WT and the known limitations of biopsy, upfront biopsy or resection is discouraged in this study. However open biopsy or definitive surgical resection is mandated by week 12 for all patients in the study. Review of the NWTS-4 cohort of patients with synchronous bilateral WT identified 38 patients with progressive or nonresponsive disease, who had a median of 7 months of therapy before surgery. Pathology at eventual surgery revealed histologic subtypes (anaplasia or rhabdomyomatous or differentiated stromal tumors) that could have benefited from earlier surgery.[185] In the patients with bilateral WT with anaplasia from the NWTS-4, core needle biopsy did not identify anaplasia in seven of seven children, whereas open biopsy or complete nephrectomy identified anaplasia in 10 of 18 at initial diagnosis. In 20 of 24 there was discordance in histology between kidneys.[186] In the AREN0534 study chemotherapy after surgery is tailored according to histologic response, on the basis of the postchemotherapy risk classification schema developed by the SIOP group.

Recurrent Wilms Tumor

Approximately 10% of patients with favorable-histology WT and 50% of patients with anaplastic WT develop recurrent disease. The survival rate after recurrence depends on several factors, including histology, time from diagnosis to recurrence, initial stage and treatment regimen, and site of recurrence.[187,188] The NWTS-5 study included treatment of recurrent WT. Patients with favorable-histology WT whose initial treatment consisted of vincristine and dactinomycin received vincristine, doxorubicin, cyclophosphamide, etoposide, and radiation therapy as salvage therapy, resulting in 4-year event-free and overall survival estimates of 71.1% and 81.8%, respectively.[189] Patients whose initial treatment was vincristine, dactinomycin, doxorubicin, and radiation therapy received a salvage regimen of alternating cyclophosphamide and etoposide, and carboplatin and etoposide, resulting in 4-year event-free survival rates and overall survival rates of 42.3% and 48.0%, respectively.[190] Interestingly female patients had better event-free survival rates and overall survival rates (54.7 and 58.7%) than male patients (28.6% and 38.0%). Other studies have demonstrated the efficacy of ifosfamide, carboplatin, and etoposide chemotherapy in the treatment of recurrent WT.[191,192] A phase II trial of topotecan demonstrated a response rate of 48% in patients with multiply recurrent favorable-histology WT.[176] The outcomes of patients with recurrent anaplastic WT are poor, with salvage rates on the order of 10%. Because upfront therapy for anaplastic WT involves the known active agents, patients with recurrent disease are candidates for phase 1 and 2 studies.

An unresolved question is whether high-dose chemotherapy with autologous stem cell rescue provides a benefit for patients with recurrent WT. Several series have reported survival rates of approximately 60% in patients with recurrent WT using single or tandem transplants.[193-195] However similar results have been attained without high-dose therapy, so the benefit of high-dose therapy remains undefined.[196] Efforts toward a randomized clinical trial to answer this question have been hampered by patient numbers. A meta-analysis of 100 patients from six studies attempted to determine characteristics of patients that predict survival with high-dose therapy and autologous stem cell rescue, comparing these patients to the published outcomes of the patients in the NWTS-5 relapse study who were treated for relapse without autologous stem cell transplant. The 4-year survival rate in the group of patients who underwent transplant was 54%. Patients who relapsed in the lung only who underwent transplant had a significantly higher 4-year survival rate (77.7%) than those with relapse in other locations or multiple relapses (4-year survival rate: 41.6%) who were treated with high-dose therapy and stem cell transplant. In comparison with the NWTS-5 cohort, 4-year survival rates were higher for stages I and II patients treated with salvage chemotherapy rather than with transplant, but the outcomes for patients with stages III through IV disease were comparable with both treatment approaches.[197] A second meta-analysis divided patients with relapse WT into three risk groups. Only patients who received four or more drugs for initial therapy or for previous relapse seemed to benefit from high-dose therapy and stem cell rescue.[198]

Most WT relapses occur within 2 years from diagnosis, but a small number of patients experience late relapse. A review of children registered in 10 national or international cooperative clinical trials identified 70 of 13,330 with relapse more than 5 years after initial diagnosis. The median time to diagnosis of this group was 13.2 years. Outcome after late relapse was most influenced by site of relapse, with an 87% survival rate in the 15 patients with relapse in the contralateral kidney and 47% for all other patients.[199]

Late Effects of Wilms Tumor Treatment

The excellent relapse-free survival rate for favorable-histology WT heightens the importance of minimizing long-term effects of treatment. Follow-up of the NWTSG cohort has identified several treatment-related effects that current studies are aiming to minimize.

One of the most feared complications of WT therapy is cardiotoxicity. The cumulative frequency of congestive heart failure in patients treated in NWTS-1 through -4 was 4.4% at 20 years for patients treated initially with doxorubicin and 17.4% for patients treated with doxorubicin for recurrent disease.[200] The risk for congestive heart failure was strongly associated with female sex (relative risk 4.5 compared with male subjects), cumulative doxorubicin dose (relative risk 3.3 for each 100 mg/m^2); lung radiation (relative risk 1.6), and left abdominal radiation (relative risk 1.8).[201]

A second major complication of WT therapy is second malignant neoplasms (SMNs). The 15-year cumulative incidence of SMN in WT survivors treated in NWTSG studies between 1969 and 1991 was 1.6% and increasing steadily.[202] The SMNs observed in this series were sarcomas, carcinomas, leukemias, lymphomas, and brain tumors. Although no cases of leukemia or lymphoma were seen after 8 years, the risk of developing a solid tumor continued to increase with time. Abdominal radiation increased the risk of SMNs, with doxorubicin potentiating the effect. Each 10 Gy of abdominal radiation therapy was estimated to increase the SMN incidence by 22% without doxorubicin and by 66% with doxorubicin. An international cohort of North American, British, and Nordic subjects between 1960 and 2004 found similar results, with a standardized incidence ration of 5.1 and 5 for solid tumors and leukemias, respectively. The leukemia risk was highest in the first 5 years after treatment, but the solid tumor risk increased with age after diagnosis. Leukemia rates were highest for those diagnosed after 1990, and rates of solid tumors were lower for those diagnosed after 1980. This may reflect the increase in intensity of chemotherapy regimens and decreased use of radiation therapy.[203]

Renal failure is a concern for WT survivors because patients undergo nephrectomy or partial nephrectomy as part of their treatment. However the cumulative incidence of end-stage renal disease (ESRD) at 20 years after WT diagnosis is only 0.6% among patients with nonsyndromic unilateral WT.[177] A small cohort of patients followed up to 5 decades after nephrectomy for childhood unilateral renal tumor demonstrated mild to moderate renal function loss, increasing from the third to fifth decade.[204] The cumulative incidence of ESRD is much higher for patients with unilateral WT and WAGR syndrome (36%), Denys-Drash syndrome (74%, but this is probably an underestimate due to inaccurate classification of the syndrome), and isolated genitourinary anomalies (7%).[177] The cumulative incidence of ESRD is also high among patients with non-syndromic bilateral WT (12%). The high rate of renal failure among patients with bilateral WT is related mainly to bilateral nephrectomies performed for tumor control.[205] However the renal failure seen with WAGR and Denys-Drash syndromes is caused by underlying renal pathology.[206,207] In the follow-up of 173 children enrolled in NWTS who developed ESRD, treatment and outcomes were very different in the 55 patients who developed ESRD from progressive bilateral WT than in the 118 who had ESRD from other causes (grouped as chronic kidney disease).[208] Of the 55 subjects with PBWT, 25 died while on initial ESRD treatment with dialysis, all but four of these as a result of WT. Only 47% of these patients had a renal transplant at 5 years. In the 118 patients with ESRD from chronic kidney disease, 77% had received a transplant at 5 years, and the survival at 10 years was 73%. Once renal transplant had been performed, the differences in outcome between the patients with progressive bilateral WT and those with chronic kidney disease were markedly reduced, suggesting that renal transplant should be considered earlier for some patients rather than waiting the 1- to 2-year tumor-free interval, as is commonly recommended.

A review of pregnancy outcomes in patients treated in NWTS-1 through -4 revealed that fetal malposition and early or threatened labor were more frequent among women who received abdominal irradiation compared with unirradiated women.[207] There were an excessive number of infants born before 36 weeks of gestation to women who received flank radiation and an excessive number of infants with birth weight below 2500 g. Most of the birth weights were appropriate for gestational age. Congenital malformations were more frequent among the offspring of women who received flank radiation compared with those of unirradiated women. Fertility was related to the dose and field of radiation therapy.[209] In general fertility is preserved in WT survivors after upper abdominal radiation that does not include the pelvis and flank, rather than whole-abdominal radiation.

Dental abnormalities (e.g., root stunting, enamel hypoplasia, microdontia) in excess of the expected incidence in control patients were observed in WT survivors.[210] A small study of 49 WT survivors revealed osteopenia in 27%.[211] Stature loss has been observed in WT survivors, with a predicted height deficit at age 18 years of 1.8 cm for children treated with 10 Gy to the flank at age 4 years.[212] Height deficits were negatively correlated with age (greater deficit with younger age of irradiation) and positively correlated with radiation dosage. Unlike cardiac effects or second malignancies, doxorubicin did not exacerbate reduction in stature.

Additional late effects were assessed in the Childhood Cancer Survivor Study, through the 25-year follow-up of childhood WT.[213] This study assessed chronic health conditions, health status, health care utilization, socioeconomic status, SMNs, and mortality of WT survivors diagnosed from 1970 to 1986. In this cohort there was a cumulative incidence of all and severe chronic health conditions of 65.4% and 24.2% at 25 years. WT survivors reported more adverse general health status than the sibling group, but mental health status, socioeconomic outcome, and health care utilization were similar. There was a 3% cumulative incidence of SMN and 6.1% incidence of mortality. Radiation exposure increased the likelihood of congestive heart failure (with and without doxorubicin), as well as occurrence of SMN and death.

CLEAR CELL SARCOMA OF THE KIDNEY

Epidemiology

The average age of onset of CCSK in the NWTSG experience was 36 months, with a range of 2 months to 14 years. In contrast to WT, a male predominance was noted, with a male-to-female ratio of 2 to 1. In a review of published series and cases reports of CCSK, no familial cases were described, and only three cases were bilateral. Because these were all in patients with widely disseminated disease, they may have represented metastatic disease rather than second primary tumors.[28,214]

Molecular Biology and Genetics

The genetic etiology of CCSK is poorly understood. Most cases of CCSK have normal karyotypes, although a recurrent t(10;17) translocation has been identified in 10% to 15% of CCSK, resulting in a fusion transcript of the *YWHAE* and *FAM22* genes.[33] Although the *TP53* gene is located at the 17p13 breakpoint of these translocations, p53 is not thought to play a prominent role in the pathogenesis of CCSK because most CCSK tumors lack detectable p53 protein by immunostaining,[28,215,216] *TP53* mutations are infrequently detected by sequencing analysis,[216] and CCSK primary cell cultures have a functional p53 pathway in response to DNA damage.[217] Other recurrent abnormalities detected by either conventional karyotyping or comparative genomic hybridization include chromosome 14q deletion (two cases) and 1q gain (three cases).[217-219]

Gene expression analysis of CCSK tumors has revealed frequent upregulation of neural markers with activation of the sonic hedgehog and phosphosinositide-3-kinase/Akt pathways.[220] Among the upregulated members of the Akt signaling pathway was the epidermal growth factor receptor *(EGFR)* gene. A subsequent study found EGFR protein immunoreactivity in 12 of 12 CCSK samples, *EGFR* gene amplification in 1 of 12 samples, and a somatic *EGFR* mutation in one sample.[221] Two samples had mutations of *PTEN*, a negative regulator of the Akt pathway.[221] These results provide a rationale for evaluating EGFR inhibitors in patients with CCSK that is refractory to current treatment modalities.

Clinical Presentation and Diagnostic Evaluation

Although CCSK has been termed the "bone-metastasizing renal tumor of childhood," metastatic disease at the time of initial presentation is distinctly uncommon. Only 4% of patients have distant metastatic disease at diagnosis, with bone, lung, and liver as the most common sites.[28] However approximately 30% of patients who undergo local lymph node sampling are found to have tumor involvement in the renal hilar and periaortic lymph nodes.[28] The value of bone scan versus skeletal survey to detect bone metastases has been addressed. Most lesions are detectable by both modalities, but some lesions are seen by only one of the two modalities.[222] Despite the predilection of this tumor to bone, bone marrow involvement is uncommon and bone marrow aspiration is no longer recommended as part of the staging workup.

Treatment

Although considered one of the unfavorable-histology renal tumors, significant progress has been made in the treatment of CCSK. Data from NWTS-1, -2, and -3 suggested that the addition of doxorubicin to the combination of vincristine and dactinomycin improved the 6-year relapse-free survival rate percentage.[223] The beneficial effect of doxorubicin was confirmed in a retrospective review of 351 cases, including 182 cases from NWTS-1 through -4.[28] NWTS-3 demonstrated no improvement in outcomes of patients with CCSK when cyclophosphamide was added to the combination of vincristine, dactinomycin, and doxorubicin.[223] However, the cyclophosphamide was delivered at a relatively low dosage and intensity. NWTS-4 asked whether the duration of therapy affects outcome for patients with CCSK. Compared with 6 months of vincristine, dactinomycin, and doxorubicin therapy, 15 months of therapy was associated with a trend toward improved 8-year relapse-free survival rate (87.8% versus 60.6%, $P = .08$), although there was no difference in 8-year overall survival rate (87.5% vs. 85.9%).[224] NWTS-5 treated patients with 6 months of a combination of vincristine, doxorubicin, and cyclophosphamide alternating with a combination of cyclophosphamide and etoposide. Preliminary analysis showed 5-year event-free and overall survival estimates of 79% and 89%, respectively.[225] Interestingly 14 patients had stage I disease, and none of these patients relapsed. An aim of the COG AREN0321 study was to assess whether the outstanding outcomes for stage I patients can be maintained without flank radiation therapy. This study closed to accrual in 2013, and outcome data are pending.

The treatment and outcomes of 191 patients with CCSK were reported from the SIOP 93-01 and SIOP 2001 protocols.[226] Significant discordance in initial pathology diagnosis and SIOP panel pathology diagnosis was noted. Of the CCSK patients 27% were initially diagnosed as a different renal tumor type, and seven cases of CCSK were changed to another tumor type by panel pathologists. Of 191 subjects, 169 received SIOP preoperative chemotherapy (recommended therapy vincristine and dactinomycin for 4 weeks for localized disease and vincristine, dactinomycin, and doxorubicin for 6 weeks for metastatic disease). Through evaluation with Response Evaluation Criteria in Solid Tumors (RECIST) criteria, 21% had a partial response after preoperative chemotherapy, 15% had minor response, 31% had stable disease, and 33% had progressive disease. All patients underwent total nephrectomy, and 189 of 191 received postoperative chemotherapy. Recommended postoperative chemotherapy was a three- or four-drug therapy regimen. Abdominal radiation therapy (mean dose of 25.2 Gy) was given to 85 patients, 2 of 71 stage 1 patients, 33 of 43 stage II patients, 44 of 50 stage III patients, and 4 of 13 stage IV patients. Five-year event-free survival and overall survival rates were 78% and 86%, respectively. The brain and lung were the most common sites of relapse, followed by bone and primary site. Five-year event-free survival and overall survival rates varied by stage as follows: stage I 79% and 87%, stage II 92% and 91%, stage III 69% and 82%, stage IV 58% and 73%. The timing of full staging in patients varied, insofar as almost all received preoperative chemotherapy for a presumed diagnosis of WT, and bone scans and brain imaging were not done routinely before starting therapy. Patients younger than 12 months were noted to have worse outcomes, with five-year event-free survival and overall survival rates of 49% and 61%.

An interesting observation on recent CCSK trials has been a shift in the site of recurrent disease. Although CCSK is associated with bone metastases, the brain has now surpassed bone as the most common site of recurrence in North American and European studies.[225,227,228] The reason for this shift is unclear, but it is possible that improved disease control outside the central nervous system has uncovered the brain as a sanctuary site for tumor cells.

MALIGNANT RHABDOID TUMOR

Epidemiology

MRT occurs primarily in infants, with a mean age of diagnosis of 15 months.[229] However, older children and rare adults with MRT have been reported. MRT is associated with mutations of the *SNF5* gene at chromosome 22q11.1, and familial MRT has been described.[230] A recent report of three individuals with MRT whose parents shared a common site of employment raises the possibility of an environmental etiology.[231]

Molecular Biology and Genetics

MRTs most frequently occur in the kidney, where they are referred to as *rhabdoid tumor of the kidney,* and the central nervous system, where they are referred to as *atypical teratoid/rhabdoid tumors,* but they can also occur in soft tissues throughout the body, where they are generally referred to as *extrarenal rhabdoid tumors*. It had long been debated whether renal, central nervous system, and extrarenal rhabdoid tumors are distinct cancers that possess similar histologic appearances or whether they are the same cancer in different anatomic locations. This issue was largely resolved when the majority of rhabdoid tumors from all anatomic sites were found to have specific biallelic inactivating mutations in *SMARCB1* (also known as *INI1*, *BAF47* and *HSNF5*).[232,233] Inactivating mutations in both copies of *SMARCB1* occur in 70% of MRT and an additional 20% to 25% of the tumors do not express SMARCB1 protein even though a specific mutation cannot be identified.[234] Whereas loss of *SMARCB1* occurs in the majority of MRTs, mutation of other genes such as *SMARCA4(BRG1)* account for a minority of cases.[235,236]

Constitutional mutation in one allele of *SMARCB1* is the basis of familial MRT, a condition termed *rhabdoid predisposition syndrome*.[237,238] Carriers have a markedly increased risk for MRT in all sites and can present with more than one primary tumor. Invariably, the second *SMARCB1* allele has been inactivated in these cancers. Constitutional mutation also accounts for the approximately 15% of patients who, after treatment for MRT, develop a second primary MRT. The frequency of germline mutations in patients presenting with new onset rhabdoid tumor is somewhat unclear. It has been reported to be present in as many as 33% (16 of 49) of cases, although this number is likely inflated by selection bias.[234] Patients who carry a germline *SMARCB1* mutation typically present with early onset rhabdoid tumor. Most, but not all, of these individuals are diagnosed before 1 year of age. Given the relatively high frequency of germline *SMARCB1* mutations, patients with new-onset MRT should have their brain and kidneys imaged to rule out additional tumors. Sequencing the *Smarc* gene from the peripheral blood of newly diagnosed patients should also be considered to rule out a constitutional mutation. If a constitutional mutation is identified, other family members should be screened for this mutation. Notably although familial studies have identified cancer-free carriers, three families with multiple siblings affected by *SMARCB1* mutant MRT have been identified in which neither of the parents carried a *SMARCB1* mutation. This suggests that gonadal mosaicism in a parent can be the basis of familial cases. Consequently the absence of a constitutional mutation in the parents of a patient with a germline *SMARCB1* mutation does not fully exclude the possibility that siblings may be affected.

SMARCB1 encodes a core member of the SWI/SNF chromatin remodeling complex. Tightly compacted chromatin provides an organizational structure for DNA but constitutes a significant barrier to gene expression. Nucleosomes, consisting of 147 base pairs of DNA wrapped around an octamer of histones, are a fundamental unit of chromatin. The SWI/SNF complex regulates transcription of specific targets by using the energy of adenosine triphosphate hydrolysis to mobilize nucleosomes and thereby control access of the transcriptional machinery to promoters. Mice heterozygous for *Snf5* are predisposed to the formation of rhabdoid tumors that display a histologic appearance essentially indistinguishable from human MRT.[239-241] Further, conditional inactivation of both Snf5 alleles leads to the extremely rapid formation of cancer, with 100% of mice developing either lymphoma or MRT at a median onset of only 11 weeks. Because the SWI/SNF complex regulates expression of many genes, the precise genes involved in the development of MRT remain to be elucidated. Evidence suggests that the cyclinD1/p16INK4a, aurora kinase A, interferon, and sonic hedgehog pathways are downstream of SMARCB1 and are dysregulated in MRT.[242-248]

Clinical Presentation and Diagnostic Evaluation

Children with MRT of the kidney present with signs and symptoms related to an intrarenal mass. Because of the young age at presentation, it is difficult to assess pain, yet most parents report fussiness. About 60% of patients have gross hematuria, which contrasts with WT in which only 20% have hematuria.[249] Fever is a presenting feature in 50% of patients, and hypertension is seen in up to 70%. Because MRT of the kidney can be associated with involvement of the central nervous system, patients may present with focal neurologic signs or signs of increased intracranial pressure.

The diagnosis of MRT must be made by histologic confirmation, although several laboratory features are suggestive of MRT. Approximately 25% of patients have hypercalcemia and 55% have hemoglobin levels less than 9g/dL. Gross or microscopic hematuria is evident in 75% of patients. The most common sites of MRT metastasis are the lung, bone, and brain. Many of the central nervous system lesions likely represent second primary tumors rather than metastatic disease. The staging evaluation for MRT therefore includes a CT scan of the chest, abdomen, and pelvis; ultrasound of the abdomen to evaluate for tumor thrombus; bone scan; and magnetic resonance imaging of the brain. Bone marrow aspirates and biopsies are not routinely required.

Treatment

MRT is one of the most lethal and aggressive pediatric cancers. Patients with rhabdoid tumor of the kidney historically were treated in NWTSG trials with vincristine, dactinomycin, and doxorubicin, with or without cyclophosphamide. The outcomes attained with these agents were poor (see Table 54-8).[229,250] In an attempt to improve on these results, NWTS-5 tested a treatment regimen consisting of carboplatin and etoposide, alternating with cyclophosphamide, but this regimen did not yield improved survival rates compared with previous regimens.[229] Case reports have highlighted patients with metastatic rhabdoid tumor who had durable survival after treatment with various combinations of ifosfamide, etoposide, carboplatin, vincristine, doxorubicin, and cyclophosphamide.[251-254] Survivors treated with high-dose therapy and autologous stem cell rescue have also been reported,[254] but it is unclear whether this provides a benefit compared with intensive regimens of standard-dose chemotherapy. On the basis of this limited experience, the COG AREN0321 study aimed to test the efficacy of the combination of cyclophosphamide, carboplatin, and etoposide alternating with vincristine, doxorubicin, and cyclophosphamide. The protocol opened in 2006 and accrued 39 patients with MRT of the kidney before permanent closure in 2013. Outcome data are still pending. A window phase of treatment with vincristine and irinotecan was trialed on this protocol for stage IV MRT, but it did not demonstrate activity in these patients. SIOP reported survival data on 107 patients with MRT treated on the SIOP 93-01 and 2001 (1993-2005).[255] Of these patients 22% had surgery performed at time of diagnosis, 62% received vincristine/dactinomycin (VA) therapy for 4 weeks prior to surgery, and 38% received vincristine/dactinomycin/doxorubicin (VAD) for 6 weeks before surgery. Postoperative treatment recommendations included four-drug therapy with etoposide, carboplatin, cyclophosphamide or ifosfamide, and doxorubicin or epirubicin. Five-year event-free survival and overall survival rates were 22% and 26%. Most patients demonstrated evidence of chemosensitivity with marked tumor reduction with initial chemotherapy, but this did not correlate with increased survival. The median time from diagnosis to relapse was 8 months, and survival after relapse was markedly poor (4 of 60, 1 to 5 years from relapse). Advanced tumor stage and young patient age were significant poor prognostic factors.

The lack of treatment uniformity among reported patients makes it difficult to determine if radiotherapy is effective for MRT. In NWTS-1 through -5, radiation therapy was given to the flank or abdomen at total doses of 1080 to 3500 cGy, yet no relationship was observed between dose and outcome.[229] Radiation therapy is a cornerstone of treatment for central nervous system rhabdoid tumors, and some suggest that the high doses delivered to the posterior fossa improve patients' outcomes.

RENAL CELL CARCINOMA

Epidemiology

Two European registries of childhood RCC revealed that the median age of diagnosis in children and adolescents was 10 to 11 years, with a male-to-female ratio of 1 to 1.1.[256,257] Among the first 3250 patients enrolled in the COG Renal Tumor Biology Study AREN03B2, 3.8% had RCC. In adults clear cell RCC, associated with mutations of the von Hippel Lindau gene, is the predominant type of RCC. In children the clear cell subtype is uncommon.[258,259] An association between oncocytoid RCC and a previous history of neuroblastoma has been described.[62,260] Translocation RCC, associated with translocations involving the *TFE3* (chromosome Xp11.1) or *TFEB* (chromosome) genes, has been associated with previous exposure to chemotherapy.[261] The evolving characterization of translocation RCC revealed that a large percentage (up to two thirds) of pediatric RCC falls within this subtype.[258,259]

Molecular Biology and Genetics

The molecular pathogenesis of the Xp11.2 and t(6:11) translocation carcinomas is an area of active study.

Xp11.2 and t(6:11) (p21:q12) Translocation Carcinomas

The fusion partners of *TFE3* have variable functions. *PSF* and *NonO* are splicing factor genes.[262] *PRCC* and *ASPL* are novel genes of unknown function, but the former may also be involved in splicing.[263-266] The clathrin heavy chain gene (*CLTC*) trimerizes with a single light chain to form clathrin, the major protein constituent of the coat that surrounds organelles (cytoplasmic vesicles) to mediate selective protein transport.[267] All TFE3 fusion proteins retain the C-terminal portion of TFE3, including its leucine-zipper dimerization domain, nuclear localization signal, and DNA binding domain. It is likely that the genes fused 5' to *TFE3* contribute strong promoters that cause overexpression of the chimeric protein, as suggested by results with TFE3 immunohistochemistry. Both PRCC-TFE3[268] and ASPL-TFE3 fusion proteins[269] localize to the nucleus and can act as aberrant transcription factors. PRCC-TFE3 may also interfere with splicing and mitotic checkpoint control through protein-protein interactions.[270]

Both ASPS and the t(X;17) renal carcinomas feature one of two types of *ASPL-TFE3* fusion transcript, in which the *ASPL* gene is fused to *TFE3* exon 4 (type 1 fusion) or *TFE3* exon 3 (type 2 fusion). Four types of *PRCC-TFE3* fusion transcripts have been described. Significant differences in clinicopathologic features between cases with different fusion types have yet to be established. Both *ASPL-TFE3* and *PRCC-TFE3* fusion transcripts are readily detected by conventional RT-PCR using appropriate primers, as described in detail elsewhere.[49,50]

A recent gene expression study has identified several novel genes that are differentially expressed between the Xp11 translocation carcinomas and conventional renal carcinomas and has shown that Xp11 translocation carcinomas may be more similar to ASPS than to conventional renal carcinomas.[271] Additionally gene expression profiling has identified potential therapeutic targets in the Xp11 translocation RCC. For example the ASPL-TFE3 fusion protein transactivates the promoter of the MET receptor tyrosine kinase, leading to MET protein overexpression. Inhibition of the MET receptor tyrosine kinase may therefore be a potential avenue of targeted therapy for these RCCs.[272]

The characteristic t(6;11)(p21;q12) translocation fuses the *Alpha* gene, an intronless gene of unknown function at 11q12, with the first intron of the *TFEB* transcription factor gene at 6p21. The breakpoint on *TFEB* is just upstream of the *TFEB* initiation ATG codon, which results in retention of the entire *TFEB* coding region in the fusion. Although the *Alpha* promoter drives expression of the fusion gene, the *Alpha* gene does not contribute to the open reading frame. Therefore the consequence of the *Alpha-TFEB* fusion is dysregulated expression of the normal full-length TFEB protein. These findings explain why the t(6;11) renal carcinomas demonstrate specific nuclear labeling for TFEB protein by IHC whereas other neoplasms and normal tissues do not. The association of both the Xp11.2 and the t(6;11) renal translocation carcinomas with exposure of the child to prior chemotherapy raises the possibility that the *TFE3* and *TFEB* loci may be particularly susceptible to DNA damage that promotes chromosome translocations.[261]

It is now thought that the t(6;11) renal carcinomas are related to the Xp11-translocation carcinomas based on the following findings:

1. Their clinical predilection to affect young patients is similar.
2. Their morphology is similar. Both neoplasms are composed of nests of predominantly clear to eosinophilic epithelioid cells, typical of a conventional RCC on routine hematoxylin and eosin sections.

3. Their immunohistohemical profiles are similar. Given their epithelioid morphology, both tumors underexpress epithelial IHC markers (cytokeratins, EMA). Several Xp11-translocation carcinomas (specifically, those with PSF-TFE3 and CLTC-TFE3 fusions) have expressed melanocytic markers by IHC, just as the t(6;11) renal neoplasms characteristically do. Both RCCs express cathepsin K in contrast to other RCC subtypes. Both RCCs overexpress proteins in the MiTF/TFE transcription factor family (TFE3 fusion proteins or native TFEB), and in each case a routine IHC assay detects this overexpression in a highly sensitive and specific fashion.
4. Their molecular pathologies are related. TFEB, TFE3, TFEC, and Mitf are members of the microphthalmia subfamily of basic helix-loop-helix transcription factors, which have homologous DNA binding domains and in fact bind to a common DNA sequence.[273] Members of the MiTF/TFE transcription factor family homodimerize and heterodimerize in all combinations to bind similar or identical DNA sequences. Therefore it seems likely that the transcription factors that are overexpressed in these two tumors (TFE3 fusion proteins and native TFEB) have similar downstream targets. Most of these targets remain to be determined; however, genes normally expressed in melanocytic differentiation may be one such example. In cell line transfection assays, overexpression of TFE3 activates the promoter of the tyrosinase gene, whereas both TFEB and TFE3 activate the promoter of the tyrosinase-related protein 1 gene.[274] The genes encoding tyrosinase and tyrosinase-related protein 1 are normally expressed in melanocyte differentiation, where they are regulated by another MiTF/TFE family member, MiTF. These results suggest that aberrant overexpression of TFEB may be responsible for the expression of melanocytic markers, a characteristic and distinctive feature of the t(6;11) renal carcinomas, and that some specific TFE3 fusion proteins may do so as well. Mouse knockout studies provide further evidence that MiTF family members may functionally overlap in certain cell types. In these studies severe osteopetrosis occurs in mice with combined TFE3 and MiTF inactivation, but there is no effect of TFE3 or MiTF loss individually on osteoclasts.[275]

Therefore, based on the preceding facts, it has been suggested that the t(6;11) renal carcinomas and the Xp11.2 translocation carcinomas should be classified as members of the "MiT translocation carcinoma family."[276] This suggestion was adopted by the 2012 International Society of Urologic Pathology Consensus Conference in Vancouver, British Columbia.

Clinical Presentation and Diagnostic Evaluation

The most common presenting signs and symptoms of pediatric RCC are flank or abdominal pain, hematuria, fever, nausea and vomiting, abdominal mass, anemia, pallor, and malaise.[256,257] It is unusual for children to present with the typical adult RCC triad of abdominal mass, hematuria, and hypertension. Approximately 20% of patients have locoregional lymph node metastases, and as many as 30% have distant metastatic disease at initial presentation. The lung, mediastinum, and liver are the most common sites of distant spread, but osseous, central nervous system, and other soft tissue metastases are also possible.[257,277] The imaging workup for pediatric RCC therefore includes CT of the chest, abdomen, and pelvis, with consideration of a bone scan and magnetic resonance imaging of the head. The role of PET scan has not been fully determined, but some forms of pediatric RCC have been found to be PET active. CT imaging has been demonstrated to have a high specificity but relatively low sensitivity for detection of local lymph nodes in pediatric RCC, underlining the importance of lymph node sampling at surgery, insofar as pathologically confirmed nodal disease can be observed even with small primary tumors (COG AREN03B2 study, unpublished observations).

Treatment

Several series of pediatric RCC have demonstrated stage-for-stage outcomes that mirror outcomes observed in adult patients.[256,257,277] Survival rates for patients with stage I, II, III, and IV disease are about 92%, 85%, 73%, and 13%, respectively.[277] A difference between adult and pediatric RCC is the prognostic significance of local lymph node involvement in the absence of distant metastases.[277] Whereas the survival rate for adult patients with local lymph node involvement is in the 20% to 30% range, approximately 75% of children with local lymph node involvement survive.[257,277] This difference likely reflects the disparate histologies between adult and pediatric RCC. Given the good outcomes of children with localized RCC and the lack of agents with known efficacy, the COG AREN0321 study recommended treating such patients without adjuvant therapy. Patients with metastatic RCC are treated according to the physician's professional judgment. The study was open from 2006 to 2013, and outcome data are pending.

Historically, the only therapy with proven benefit for metastatic RCC was immunotherapy using interleukin-2, interferon-alpha, or a combination of these agents. However immunotherapy produces tumor responses in only 10% to 20% of patients, most of whom achieve a transient response and experience substantial toxicity.[278] With the development of drugs targeted to signal transduction and tumor-related angiogenesis, multiple trials have response rates and impact on progression-free survival in adult RCC. Agents that have demonstrated benefit in some studies of adult RCC include vascular endothelial growth factor pathway inhibitors (sorafenib, sunitinib, pazopanib, axitinib, and bevacizumab) and mTOR inhibitors (temsirolimus and everolimus). In the wake of these studies, molecularly targeted therapy has become the frontline treatment for advanced RCC in adult patients. However in considering treatment of pediatric RCC, the clinician must remember that childhood and adult RCC are distinct entities. Most of the patients enrolled in adult studies had the clear cell subtype of RCC, whereas the majority of pediatric RCC patients have the translocation or papillary subtypes. A retrospective series from the Juvenile RCC Network indicated that tyrosine kinase inhibitors, most notably sunitinib, have produced objective responses or disease stabilization in translocation RCC.[279] A prospective trial of tyrosine kinase inhibition therapy for metastatic or recurrent translocation RCC is under development by the COG.

A category of pediatric RCC with a distinctly poor outcome is renal medullary carcinoma, which is observed in patients with sickle cell trait.[61] Patients with renal medullary carcinoma almost always present with metastatic disease and have fatal outcomes. Transient responses have been observed after chemotherapy treatment with a combination of methotrexate, vinblastine, doxorubicin, and cisplatin[280-282] and a combination of platinum, gemcitabine, and taxane.[283,284] Agents that target the ABL tyrosine kinase may be considered for investigation in renal medullary carcinoma because these tumors have been reported to have ABL gene amplification and BCR-ABL rearrangements.[281,282] A tumor also recently was found to have a translocation involving the *ALK* gene.[285] A patient with renal medullary carcinoma was shown to have a complete tumor response after treatment with the proteosome inhibitor bortezomib.[286]

CONGENITAL MESOBLASTIC NEPHROMA

Epidemiology

The average age of diagnosis of CMN is 3.4 months. The vast majority of cases are diagnosed in infancy, but in rare cases children up to 9 years of age have been diagnosed. Congenital malformations accompanied 14% of CMN cases, including genitourinary and gastrointestinal anomalies, polydactyly, and hydrocephalus.[287] There is a strong correlation of age at diagnosis and histologic subtype; the cellular type is seen more commonly in children older than 3 months of age.[288]

Molecular Biology and Genetics

IFS and cellular CMN have much in common. The two neoplasms have virtually indistinguishable morphology and affect the same young age group. Both also are associated with a prognosis that is better than that expected given their ominous-appearing morphology; both IFS and cellular CMN only rarely metastasize. There had also been molecular hints of a relationship between IFS and cellular CMN, insofar as both tumors are characterized by polysomies, particularly of chromosomes 11, 17, and 20.[289,290]

A major advance occurred in 1998, when it was discovered that IFS is characterized by a specific t(12;15)(p13;q25). The t(12;15) results in fusion of the *ETV6* gene on chromosome 12 with the *NTRK3* gene on chromosome 15.[291] The *ETV6 (TEL)* gene had previously been implicated in the t(12;21)(p13;q22) of pediatric precursor B-cell acute lymphoblastic leukemia and encodes a transcription factor with a helix-loop-helix protein dimerization domain. NTRK3 is a receptor tyrosine kinase that is activated by ligand-dependent dimerization and is involved in neural development. The chimeric ETV6-NTRK3 protein is postulated to be constitutively dimerized and therefore to affect constitutively active tyrosine kinase growth pathway signaling. Significantly, neither infantile fibromatosis nor adult-type fibrosarcomas, two entities in the histologic differential diagnosis of infantile fibrosarcoma, contain this gene fusion.

Given the clinicopathologic similarities of IFS and cellular CMN, the question arose as to whether cellular CMN bore the same chromosome translocation and gene fusion. Two studies have conclusively proven this to be true.[292,293] Of 11 cellular CMNs studied, 10 contained the fusion transcript, whereas all five classic CMNs (the renal counterpart of infantile fibromatosis) did not. Hence it is tempting to consider cellular CMN to be essentially an IFS of the renal sinus. Indeed there is no clinical, morphologic, histopathologic, or genetic reason to think otherwise. Additionally these studies highlight the fact that classic and cellular CMNs are molecularly distinctive neoplasms, not just two morphologic patterns of one neoplasm, as their names would suggest. The data on mixed CMN is conflicting, but most recent studies have found an absence of the *ETV6-NTRK3* gene fusion in mixed CMN.[67,289,294]

Further studies have addressed the function of the *ETV6-NTRK3* fusion gene. Wai and colleagues have shown that ETV6-NTRK3 chimeric tyrosine kinase is capable of transforming NIH3T3 cells.[295] Tognon and colleagues have subsequently shown that this requires activation of both the Ras-Raf1-Mek1-ERK1/2 mitogenic pathway and the phosphatidylinositol 3’-kinase (PI3K)-Akt cell survival pathway, such that inhibition of either pathway abolishes transformation.[296] These findings raise the possibility that MEK or PI3K inhibitors could be potentially useful in treating the minority of patients who develop metastatic disease. Jin and coworkers have shown that the *ETVG-NTRK3* chimeric tyrosine kinase suppresses transforming growth factor(TGF) β tumor suppressor activity by binding to the type II TGF-β receptor.[297] Finally the *ETV6-NTRK3* gene fusion has also been found to be consistently present in secretory carcinoma of the breast, a rare epithelial cancer that tends to affect young people, and mammary analogue secretory carcinoma of the salivary gland.[298,299] Rare cases of acute myeloid leukemia have been shown to bear the same gene fusion.[300,301] Hence the *ETV6-NTRK3* gene fusion is remarkable in that it may apparently transform cells of the mesenchymal, epithelial, and hematopoietic lineages.

Clinical Presentation and Diagnostic Evaluation

A palpable abdominal mass is the most common presenting symptom in infants with CMN. Other signs and symptoms at presentation include hematuria (18%), hypertension (4%), anemia (4%), and vomiting (6%).[287] Hypercalcemia has been reported as a presenting feature of CMN.[302] Patients with CMN do not present with metastatic disease, although the cellular histologic type has the potential to metastasize to the lung and, rarely, the brain later in the course of the disease. A baseline chest, abdomen, and pelvis CT scan is recommended.

Treatment

Outcomes for patients with CMN are generally excellent without adjuvant therapy, with overall survival rates of 95%.[287,303] The few tumors that recur are almost exclusively the cellular type of the CMN. In addition to cellular histologic subtype, age greater than 3 months and stage III disease have been associated with relapse.

The standard therapy for all stages of classic CMN (noncellular) and stage I and II cellular CMN is surgical resection followed by observation with serial imaging studies. It remains to be established whether patients with stage III cellular CMN benefit from adjuvant chemotherapy. In a series published by the German Pediatric Oncology Group, two of five patients with stage III cellular CMN developed recurrent disease, whereas only one of the remaining 45 patients experienced recurrence.[303] Experience with presurgical treatment of CMN shows that most of these tumors respond to a combination of vincristine and dactinomycin therapy.[303] Recurrent cellular CMN tumors are responsive to combinations of vincristine, doxorubicin, and dactinomycin; vincristine, dactinomycin, and cyclophosphamide; vincristine, doxorubicin, and cyclophosphamide; and ifosfamide , carboplatin, and etoposide.[304] There is no established role for radiation therapy in the treatment of CMN.

FUTURE DIRECTIONS

A broad view of the field of pediatric renal tumors provides cause for both celebration and trepidation. Treatment of favorable-histology WT has been a terrific success, with cure rates in the 90% range. Remarkably the success has been coupled with a diminishment in treatment, thereby sparing patients of acute and long-term adverse effects. Clinicians have a more complete understanding of renal tumor biology than ever before, with the discovery of several new genes (*WTX*, *BRCA2*, *INI1*, *TFE3*, and others) and increased understanding of previously identified genes (*WT1* and the *11p15* locus). The availability of a new pipeline of molecularly targeted agents provides the opportunity to advance renal tumor therapies beyond the traditional cytotoxic agents.

On the other hand challenges remain. Outcomes for children with anaplastic WT, bilateral WT, recurrent WT, RCC, and MRT remain suboptimal (all with survival rates of less than 75%). For some of these tumor types, such as anaplastic WT and MRT, increased chemotherapy doses and intensity are approaching the maximum level of patient tolerance. Novel treatment approaches, such as molecularly targeted agents, differentiating agents, or immunotherapy, are required. A pitfall to the introduction of new agents is that the patient populations are small, so clinical trials take years to execute. New initiatives for international collaboration between the COG and SIOP will facilitate the conduct of clinical research on the uncommon pediatric renal tumors. For tumor types such as pediatric RCC, the tumor biology and natural clinical history have only recently begun to be understood. Broad support for pediatric renal tumor research is essential for further progress.

5. Vujanic GM, Sandstedt B, Harms D, et al: Revised International Society of Paediatric Oncology (SIOP) working classification of renal tumors of childhood. *MedPediatr Oncol* 38:79–82, 2002.

   This was the first article to describe the SIOP histologic classification system for pediatric renal tumors. This system is based on postchemotherapy histologic changes, including the percentage of the tumor that is necrotic and the predominant cell type (blastemal, epithelial, or stromal) after chemotherapy. By contrast, the COG system is based on prechemotherapy histology and uses only anaplasia as a histologic prognostic factor.

8. Doros LA, Rossi CT, Yang J, et al: DICER1 mutations in childhood cystic nephroma and its relationship to DICER1-renal sarcoma. *Mod Pathol* 2014 [epub ahead of print].

   This study found loss-of-function DICER1 *mutations in 14 of 20 (70%) cystic nephromas evaluated, whereas none of six CPDNs had* DICER1 *mutations. CPDN previously was considered to lie on a spectrum between cystic nephroma and WT, but these data suggest that the two cystic renal tumors are distinct entities. The authors also describe sarcomas developing within cystic nephromas, analagous to the progression from the cystic type 1 pleuropulmonary blastomas to the solid and sarcomatous type PPBs, also associated with* DICER1 *mutations.*

11. Bardeesy N, Falkoff D, Petruzzi MJ, et al: Anaplastic Wilms' tumour, a subtype displaying poor prognosis, harbours p53 gene mutations. *Nat Genet* 7:91–97, 1994.

    This study first showed an association between TP53 *mutations and anaplastic histology WT. Several lines of evidence indicate that anaplastic WT arises on a background of favorable-histology WT. About 75% of anaplastic WTs have* TP53 *mutations. Studies are under way to assess whether prognosis and biology differ between anaplastic WTs based on their TP53 mutation status.*

15. Dome JS, Cotton CA, Perlman EJ, et al: Treatment of anaplastic histology Wilms' tumor: results from the fifth National Wilms' Tumor Study. *J Clin Oncol* 24:2352–2358, 2006.

    This study demonstrates that patients with stage II through IV diffuse anaplastic WT had improved survival rates compared with historic controls using a new regimen consisting of vincristine, doxorubicin, and cyclophosphamide alternating with cyclophosphamide and etoposide. The study indicates that although anaplastic WT is relatively resistant to therapy compared with favorable-histology WT, outcomes were improved with a more intensive chemotherapy regimen. The study also showed that patients with stage I anaplastic WT fared significantly worse than patients with stage I favorable-histology WT, contrary to the previous belief.

86. Gessler M, Poustka A, Cavenee W, et al: Homozygous deletion in Wilms tumours of a zinc-finger gene identified by chromosome jumping. *Nature* 343:774–778, 1990.

    The preceding three papers describe the initial identification of the WT1 *gene and provide the first insights into its function as a transcription factor. Subsequent papers indicate that there are multiple splice variants of this gene with differing functions.*

90. Huff V: Wilms tumor genetics. *Am J Med Genet* 79:260–267, 1998.

    This is an excellent survey of germline and somatic WT1 *mutations in WT and genotype-phenotype relationships.*

93. Koesters R, Ridder R, Kopp-Schneider A, et al: Mutational activation of the β-catenin proto-oncogene is a common event in the development of Wilms tumors. *Cancer Res* 59:3880–3882, 1999.

94. Maiti S, Alam R, Amos CI, et al: Frequent association of beta-catenin and WT1 mutations in Wilms tumors. *Cancer Res* 60:6288–6292, 2000.

    The preceding two papers are the first to describe β-catenin (CTNNB1) *mutations in WT. There is a strong correlation between* β-catenin *mutations and WT1 mutations, suggesting that the two pathways collaborate in Wilms tumorigenesis.*

97. Rivera MN, Kim WJ, Wells J, et al: An X chromosome gene, WTX, is commonly inactivated in Wilms tumor. *Science* 315:642–645, 2007.

    This is the first paper to describe a relatively new WT gene, WTX. *The gene encodes a protein that acts in the WNT signaling pathway. The biology of this tumor supressor is unconventional because only one hit is required based on its location on the X chromosome.*

108. Scott J, Cowell J, Robertson ME, et al: Insulin-like growth factor-II gene expression in Wilms' tumour and embryonic tissues. *Nature* 317:260–262, 1985.

109. Reeve AE, Eccles MR, Wilkins RJ, et al: Expression of insulin-like growth factor-II transcripts in Wilms' tumour. *Nature* 317:258–260, 1985.

    The preceding two papers establish the link between the 11p15/Beckwith-Wiedemann syndrome locus and IGF2 overexpression in WT. How these alterations relate to other genetic changes observed in WT was described more recently (see Reference 118).

117. Hu Q, Gao F, Tian W, et al: Wt1 ablation and Igf2 upregulation in mice result in Wilms tumors with elevated ERK1/2 phosphorylation. *J Clin Invest* 121:174–183, 2010.

    WT has traditionally been categorized into two subtypes: those associated with WT1 mutations and those associated with alterations of the Beckwith-Wiedemann 11p15/IGF2 locus. It is now clear that the lines are blurred between the two subtypes. This paper describes one of the first genetically engineered mouse models of WT obtained by combined Wt1 ablation and Iff2 upregulation.

118. Gadd S, Huff V, Huang CC, et al: Clinically relevant subsets identified by gene expression patterns support a revised ontogenic model of Wilms tumor: a Children's Oncology Group Study. *Neoplasia* 14:742–756, 2012.

    This paper describes a detailed analysis correlating gene expression patterns with WT1 mutations, 11p15 copy number and methylation, CTNNB1 (β-catenin) mutations, and WTX mutations in more than 300 WT samples. The analysis led to a revised ontogenic model of WT consisting of five subsets with distinct clinical and biologic features.

141. Grundy PE, Green DM, Dirks AC, et al: Clinical significance of pulmonary nodules detected by CT and not CXR in patients treated for favorable histology WT on National Wilms Tumor Studies-4 and -5: a report from the Children's Oncology Group. *Pediatr Blood Cancer* 59:631–635, 2012.

    This paper describes the largest study to date on the significance of WT lung nodules detected by CT scan but not chest x-ray. The findings suggest that so-called CT-only nodules have clinical significance because patients treated with only two-drug therapy (vincristine and dactinomycin) had a significantly lower event-free survival rate compared with patients treated with three-drug therapy (vincristine, dactinomycin, and doxorubicin). The overall survival rate, however, was not different between the two groups.

149. Shamberger RC, Guthrie KA, Ritchey ML, et al: Surgery-related factors and local recurrence of Wilms tumor in National Wilms Tumor Study-4. *Ann Surg* 229:292–297, 1999.

    This study emphasizes the contribution of surgery-related factors to clinical outcomes in WT. The findings illustrate the importance of lymph node sampling in assigning appropriate therapy: patients with lymph nodes positive for WT fared better than patients with no lymph nodes sampling at all.

166. Grundy PE, Breslow NE, Li S, et al: Loss of heterozygosity for chromosomes 1p and 16q is an adverse prognostic factor in favorable-histology Wilms tumor: a report from the National Wilms Tumor Study Group. *J Clin Oncol* 23:7312–7321, 2005.

    This is the primary paper reporting outcomes for favorable-histology WT in the NWTS-5. It describes a prospective analysis of LOH at 1p and 16q as a prognostic marker. Combined LOH at both loci was found to predict inferior event-free and overall survival in all stage groups. These findings influenced the risk stratification schema for WT on the most recent generation of COG studies.

168. Green DM, Breslow NE, Beckwith JB, et al: Treatment with nephrectomy only for small, stage I/favorable histology Wilms' tumor: a report from the National Wilms' Tumor Study Group. *J Clin Oncol* 19:3719–3724, 2001.

    One of the primary objectives of the NWTS-5 was to assess whether young patients with small stage I favorable-histology WT can be treated with surgery only, without adjuvant chemotherapy. The study closed early after the predefined stopping rule for number of relapses was reached. However the salvage rate after recurrence exceeded expectations, so the overall survival rate with this approach was outstanding. This question was revisited in the recently completed COG AREN0532 study.

171. Pritchard Jones K, Graf N, Bergeron C, et al: Doxorubicin can be safely omitted from the treatment of Stage II/III intermediate risk histology Wilms Tumour: results of the SIOP 2001 randomized trial. *Pediatr Blood Cancer* 57:741, 2011.

    Although published only in abstract form at the time this chapter was written, these results are important because they will lead to a reduction in therapy for a large group of patients. The study found that withholding doxorubicin does not affect overall survival in patients with stage II and III intermediate-risk WT. It is important to recognize that these findings cannot be applied to *patients treated in COG studies because the staging and histologic classification systems differ.*

172. Beckwith JB, Palmer NF: Histopathology and prognosis of Wilms tumor. *Cancer* 41:1937–1948, 1978.

This is the first paper to associate anaplastic histology with adverse prognosis in WT. Despite the remarkable expansion of knowledge on the molecular genetics of WT, anaplasia remains the most powerful predictor of outcome.

189. Green DM, Cotton CA, Malogolowkin M, et al: Treatment of Wilms tumor relapsing after initial treatment with vincristine and actinomycin D: a report from the National Wilms Tumor Study Group. *Pediatr Blood Cancer* 48:493–499, 2007.
190. Malogolowkin M, Cotton CA, Green DM, et al: Treatment of Wilms tumor relapsing after initial treatment with vincristine, actinomycin D, and doxorubicin. A report from the National Wilms Tumor Study Group. *Pediatr Blood Cancer* 50:236–241, 2008.

The preceding two papers describe the outcomes of patients with relapsed WT treated in NWTS-5. Two primary prognostic categories emerged. Patients who were treated initially with only two-drug therapy had overall survival rates after relapse af approximately 80%. Patients treated initially with three drugs or more had overall survival rates of approximately 50% with a more intensive salvage regimen. Initial treatment overshadowed other prognostic factors for survival after recurrence, including site of recurrence and time to recurrence.

197. Presson A, Moore TB, Kempert P: Efficacy of high-dose chemotherapy and autologous stem cell transplant for recurrent Wilms' tumor: a meta-analysis. *J Pediatr Hematol Oncol* 32:454–461, 2010.
198. Ha TC, Spreafico F, Graf N, et al: An international strategy to determine the role of high dose therapy in recurrent Wilms' tumour. *Eur J Cancer* 49:194–210, 2013.

An unresolved question about the management of recurrent WT is whether high-dose therapy with autologous stem cell rescue provides benefit. Because no randomized clinical trials have been conducted, two groups conducted meta-analyses to address this question. Both analyses agree that high-dose therapy is not beneficial for relapses that occur after initial therapy with only two drugs. The greatest benefit for transplant appears to be within the group of patients who received four or more drugs before transplant—that is, those with anaplastic histology or those with multiply recurrent favorable-histology WT.

229. Tomlinson GE, Breslow NE, Dome J, et al: Rhabdoid tumor of the kidney in the National Wilms' Tumor Study: age at diagnosis as a prognostic factor. *J Clin Oncol* 23:7641–7645, 2005.

One of the largest series of rhabdoid tumor of the kidney demonstrated the lack of progress over the years treating this aggressive malignancy. Young age was established as an adverse prognostic factor.

232. Versteege I, Sevenet N, Lange J, et al: Truncating mutations of hSNF5/INI1 in aggressive paediatric cancer. *Nature* 394:203–206, 1998.

This classic paper establishes the association between SMARCB1/INI1/SNF5 *mutations and MRT. This work shows that rhabdoid tumors arising at different sites—renal, brain, and extrarenal or extra central nervous system—have a common molecular etiology.*

258. Bruder E, Passera O, Harms D, et al: Morphologic and molecular characterization of renal cell carcinoma in children and young adults. *Am J Surg Pathol* 28:1117–1132, 2004.

This paper describes the histologic subtypes of RCC in children and adolescents. It illustrates that childhood RCC is distinct from adult RCC.

291. Knezevich SR, McFadden DE, Tao W, et al: A novel ETV6-NTRK3 gene fusion in congenital fibrosarcoma. *Nat Genet* 18:184–187, 1998.
292. Knezevich SR, Garnett MJ, Pysher TJ, et al: ETV6-NTRK3 gene fusions and trisomy 11 establish a histogenetic link between mesoblastic nephroma and congenital fibrosarcoma. *Cancer Res* 58:5046–5048, 1998.
293. Rubin BP, Chen CJ, Morgan TW, et al: Congenital mesoblastic nephroma t(12;15) is associated with ETV6-NTRK3 gene fusion: cytogenetic and molecular relationship to congenital (infantile) fibrosarcoma. *Am J Pathol* 153:1451–1458, 1998.

The preceding three papers describe ETV6-NTRK3 translocations as a feature of the cellular type of CMN. These papers also establish a histogenetic link between CMN and congenital infantile fibrosarcoma. Whereas recurrence is exceedingly rare in CMN without the translocation, 20% to 25% of cases of stage III disease with the translocation experience recurrence.

Visual Outcome
Cognitive and Functional Development of Patients with Retinoblastoma
Other Late Effects

Retinoblastoma is the most frequent neoplasm of the eye in childhood and the third most common intraocular malignancy in all ages, following malignant melanoma and metastatic carcinoma. Retinoblastoma represents 2.5% to 4% of all pediatric cancers but 11% of cancers in the first year of life.[1] The average age-adjusted incidence rate of retinoblastoma in the United States and Europe is 2 to 5 per million children (approximately one in 14,000 to 18,000 live births).[2,3] Thus retinoblastoma develops in an estimated 8000 children each year worldwide.[4]

Retinoblastoma is a cancer of the very young; two thirds of all cases of retinoblastoma are diagnosed before 2 years of age, and 95% of cases are diagnosed before 5 years of age.[1] For these reasons, in addition to cure of the disease, therapeutic approaches require consideration of the need to preserve vision with minimal long-term adverse effects.

Retinoblastoma presents in two distinct clinical forms. The first form is bilateral or multifocal and heritable (occurring in 25% of all cases of retinoblastoma); it is characterized by the presence of germline mutations of the retinoblastoma-1 *(RB1)* gene. Multifocal retinoblastoma may be inherited from an affected survivor (25%), or it may be the result of a new germline mutation (75%). The second form is unilateral (representing 75% of all cases); about 85% to 90% of the cases are nonhereditary, and the remainder carry a germline *RB1* mutation.

EPIDEMIOLOGY

The incidence of retinoblastoma is not distributed equally around the world. It appears to be higher (6 to 10 cases per million children) in Africa[2,5] and India[6] and among children of Native American descent in the North American continent.[7,8] The increased incidence in those groups occurs primarily at the expense of unilateral cases. Whether these geographic variations are due to ethnic or socioeconomic factors is not known. However the fact that even in industrialized countries an increased incidence of retinoblastoma is associated with poverty and low levels of maternal education[9] suggests a role for the environment. Differences in the incidence of embryonal tumors between countries and ethnic groups have been consistently reported during the past decades, particularly for retinoblastoma[2]; however the deficiencies inherent to suboptimal cancer registries in low-income countries have made proper estimates difficult. In a country as ethnically diverse and socioeconomically heterogenous as Brazil, De Camargo and colleagues[10] calculated the age-adjusted incidence rates (AAIR) of retinoblastoma in 20 population-based cancer registries and noted higher AAIRs than those of developed countries. The AAIR for children 0 to 4 years of age was as high as 15 and 27 in Salvador and Bahia, respectively, two of the most deprived states in the country (versus 10 to 12 in the United States and Europe).[10] In a broader study testing the differences in incidence for embryonal tumors and their correlation with socioeconomic status, the same group documented an inverse correlation between the incidence of retinoblastoma and socioeconomic index. A similar phenomenon has been reported in Mexico, where a higher incidence of retinoblastoma has been documented, particularly in deprived states such as Chiapas.[11,12]

Decreased dietary intake of vegetables and fruits during pregnancy, resulting in decreased intake of nutrients such as folate and carotenoids, which are necessary for deoxyribonucleic acid (DNA) methylation and synthesis and for retinal formation, has also been associated with an increased risk of unilateral sporadic retinoblastoma.[13] In a case-control study, the risk of developing retinoblastoma was associated with a maternal polymorphism in dihydrofolate reductase (*DHFR* 19bpdel), particularly in women taking prenatal synthetic folic acid supplements.[14]

It is well known that exposure to certain toxic agents during gestation increases the frequency of germinal mutations in animals. The vast majority of germline mutations in sporadic heritable retinoblastoma are paternally derived,[15] and studies have suggested an association between paternal age[9,16,17] and occupation[18] with the occurrence of sporadic heritable retinoblastoma. Reports have also suggested an association between retinoblastoma and increased sunlight exposure,[19,20] air toxins from gasoline and diesel combustion,[21] or in vitro fertilization.[22-24] In a case-control study of sporadic retinoblastoma, radiologic studies of the abdomen leading to scattered radiation exposure of the gonads was associated with an increased risk of bilateral retinoblastoma in the child.[25]

Retinoblastoma tumors arise from fetal retinal cells that have lost function of both allelic copies of the *RB1* gene, the first of the tumor suppressor genes to be cloned. The first event may be either a germline or a somatic mutation, but the second and subsequent events are always somatic. Not all tumors have mutations in *RB1*, suggesting that there is either another gene or alternate mechanisms for inactivation of *RB1* function.[26,27] For example, the *RB1* gene can be epigenetically silenced through hypermethylation of the promoter.[28,29] In recent years, studies have suggested a role for human papillomaviruses (HPVs) in the pathogenesis of retinoblastoma. The viral oncoprotein E7 of high-risk HPV types has been shown to bind to and inactivate the *RB1* gene product. Therefore it is plausible that HPV infection could be functionally equivalent to the biallelic loss of *RB1*.[30] Transgenic mice expressing HPV16 E6 and E7 proteins develop retinoblastoma.[31] Presumably exposure to HPV would occur peripartum from genital infection of the mother. In this regard the use of barrier methods of contraception is associated with a reduced incidence of both retinoblastoma and HPV infection,[9,32] and studies have also shown a correlation with sexually transmitted diseases during pregnancy.[17] Interestingly an overlap occurs between countries in which the relative incidence of retinoblastoma is greatest and those in which the incidence of cervical carcinoma is highest.[32] High-risk HPV sequences have been detected in 28% to 36% of tumors in some populations.[32,33]

BIOLOGY OF RETINOBLASTOMA

Cellular Origins of Retinoblastoma

It is widely believed that the molecular and cellular features of a tumor reflect its cell of origin and can thus provide clues about treatment targets. Since 1897 when Wintersteiner first proposed that rosettes in retinoblastoma are reminiscent of photoreceptor differentiation,[34] the cell of origin and the cellular features of retinoblastoma have been debated. Initially the focus was on the cellular features that could be identified by histologic analyses, such as the presence of rosettes. With advances in molecular biology and biochemistry, the debate about the retinoblastoma cell of origin has been revisited, with a strong predilection toward photoreceptors being the cell of origin.[35-43] In addition to photoreceptors, a number of independent studies suggested that retinoblastomas may also have features of progenitor cells or interneurons such as amacrine cells.[38,44,45,46,47-51] The possibility of tumor cells with a hybrid molecular/cellular phenotype was not considered in those previous studies.

In a recent study of the molecular, cellular, neuroanatomic, and neurochemical features of mouse and human retinoblastoma, it was shown that they have features of multiple cell classes, principally amacrine/horizontal interneurons, retinal progenitor cells, and photoreceptors.[52] Indeed, single-cell gene expression array analysis showed that these multiple cell type-specific developmental programs are coexpressed in individual retinoblastoma cells, which creates a progenitor/neuronal hybrid cell. It is widely believed that the initiating genetic lesion in the *RB1* gene occurs in proliferating retinal progenitor cells during fetal development. Retinal progenitor cells may be the cell of origin for retinoblastoma, and the multiple differentiation programs that are found in human and mouse retinoblastomas may reflect the multipotent competence of retinal progenitor cells. Indeed in single-cell gene expression array analyses of mouse retinal progenitor cells, photoreceptor and interneuron genes were often expressed in proliferating retinal progenitor cells.[53]

The finding that retinoblastoma tumor cells express multiple neuronal differentiation programs that are normally incompatible in development suggests that the pathways that control retinal development and establish distinct cell types are perturbed during tumorigenesis. This discovery underscores the challenges of assigning cell-of-origin status without first establishing the full molecular and cellular signature of a tumor. It is important to emphasize that these studies do not necessarily indicate that a photoreceptor, interneuron, or progenitor cell is the cell of origin for retinoblastoma. Detailed cell-lineage studies combined with live imaging approaches will be required to definitively identify the cell of origin for retinoblastoma. Nonetheless, this detailed characterization of the neuronal pathways that are deregulated in retinoblastoma may provide novel targets for therapeutic intervention. This example highlights the importance of comprehensive molecular, cellular, and physiologic characterization of human cancers with single-cell resolution as we incorporate molecular targeted therapy into treatment regimens.

Retinoblastoma Tumor Cell Differentiation

Many of the previous studies on retinoblastoma tumor cell differentiation have focused on photoreceptor features, including a recent study linking the origin of retinoblastoma to cone photoreceptors.[43] As previously described, a detailed cross-species gene expression array analysis indicated that retinoblastomas express molecular features of photoreceptors and that the rod signature is more robust than the cone signature.[52] However morphometric and neuroanatomic studies of mouse and human retinoblastomas showed few cellular features of photoreceptors, which raises the possibility that the gene regulatory network that controls photoreceptors is deregulated in human retinoblastomas. Interestingly a large number of photoreceptor genes are also expressed in medulloblastomas[54,55] despite their distinct cellular origins, which may indicate that the transcriptional pathways involved in photoreceptor differentiation are nonspecifically deregulated in a variety of tumors of the central nervous system (CNS). It is not known if this "photoreceptor signature" has any prognostic or therapeutic significance in retinoblastoma or other tumors of the CNS.

Human and mouse retinoblastomas have molecular, morphometric, neuroanatomic, and neurochemical features of interneurons, including amacrine and horizontal cells.[52] Indeed, the cell-type specific features that are most common across human and mouse retinoblastomas are those related to amacrine cell differentiation. As previously discussed, the tumor's cell of origin may be completely independent of amacrine interneurons, and because tumor suppressor or oncogenic pathways are deregulated during tumorigenesis, the amacrine differentiation program may be aberrantly activated during retinoblastoma tumorigenesis.

Nonetheless, the amacrine differentiation of human and mouse retinoblastoma may be functionally significant for tumor survival and progression. The most striking evidence for amacrine differentiation at the cellular level came from the identification of dense core vesicles in human and mouse retinoblastomas in electron micrographs. Retinoblastomas produce catecholamines and other monoamines,[56-58] and several of the receptors for monoamines are expressed, as are the genes involved in the biosynthesis of monoamines. When monoamine receptors were blocked with pharmacologic agents, retinoblastoma growth was reduced in culture and in vivo. In contrast, agents that block the other major neurotransmitter signaling pathways (γ-aminobutyric acid, glycine, and glutamate) had no effect on retinoblastoma, nor did the inhibition of selective reuptake of catecholamines with pharmacologic agents. One interpretation of these data is that retinoblastoma cells are engaged in an autocrine induction of the catecholamine-signaling pathway. All of the major catecholamine/monoamine receptors are G-protein–coupled receptors and signal through adenyl cyclase–mediated cyclic adenosine monophosphate induction. This pathway can directly or indirectly stimulate the mitogen-activated protein kinase pathway and provide an important mitogenic signal for retinoblastoma. It may also explain why retinoblastomas form in the retina. That is, this tissue is uniquely susceptible to tumorigenesis because the amacrine-differentiation pathway can be co-opted for mitogenic signaling after *RB1* gene inactivation. Additional studies will be required to determine whether catecholamine signaling influences survival and growth through the mitogen-activated protein kinase pathway or if it is required for some other aspect of tumorigenesis.

Retinoblastoma Genomics and Epigenomics

Most retinoblastomas initiate with biallelic loss of the *RB1* gene.[59] *RB1* inactivation confers limitless replicative potential to retinoblasts, and these preneoplastic cells can progress to retinoblastoma by acquiring additional somatic mutations that contribute to the acquisition of new cellular properties, including evasion of cell death and senescence, sustained angiogenesis, and activation growth–signaling pathways. Several different mechanisms have been proposed to explain the rapid progression of retinoblastoma after *RB1* inactivation. In a series of studies using genetically engineered murine cells and immortalized human cells, it was shown that RB1 may play an important role in maintaining genomic stability.[60-62] Thus in some cellular contexts, inactivation of the *RB1* gene could lead to chromosome instability, allowing secondary and tertiary mutations in key cancer pathways to be rapidly acquired. Alternatively RB1 has also been implicated in a variety of epigenetic processes, so it is also possible that perturbations in the epigenetic landscape may contribute to tumorigenesis in the retina. In support of an epigenetic mechanism, recent whole-genome sequencing and integrated epigenetic analysis of human retinoblastoma revealed that the tumors have relatively stable genomes, and several cancer genes were epigenetically deregulated.[63] At least one of those epigenetically deregulated genes (spleen tyrosine kinase; *SYK*) is required for retinoblastoma tumor cell survival in vivo (discussed later).[63] These two alternative mechanisms (genome instability and epigenetic deregulation) of retinoblastoma progression are not necessarily mutually exclusive, and some tumors may show evidence of both chromosomal instability and epigenetic deregulation.

Although epigenetic deregulation of key cancer pathways has been shown to be directly relevant for retinoblastoma tumor progression, the functional significance of recurrent secondary genetic lesions is still poorly understood. During the 27 years since the *RB1* gene was cloned, researchers have focused on identifying genetic lesions in retinoblastoma that contribute to tumor progression after *RB1* inactivation.[64] Cytogenetic and array comparative genome hybridization studies have led to the identification of regions of the genome that are gained or lost in retinoblastomas and may contribute to tumorigenesis.[64] Those studies have led to the identification of candidate oncogenes and tumor suppressor genes whereby copy number variations (CNVs) correlate with changes in gene expression.[65,66] However the major limitation of those studies is their relatively small number of tumors analyzed and the modest effects on gene expression for tumors with CNVs versus those without the corresponding lesion. Even for the most common recurrently mutated gene in retinoblastoma, BCL6 corepressor *(BCOR)*, there have been no direct in vivo studies showing that it contributes to tumorigenesis.

Carefully designed in vivo experiments to explore the role of putative oncogenes and tumor suppressor genes in retinoblastoma tumorigenesis are important for advancing our understanding of the molecular mechanisms of retinoblastoma progression. For example, a recent study showed that in a small proportion (1.5%) of human unilateral nonfamilial retinoblastomas, no *RB1* gene mutations are present and they have v-myc avian myelocytomatosis viral oncogene neuroblastoma derived homolog *(MYCN)* amplification (≥10 copies).[27] The authors suggested that in those patients, *MYCN* amplification may initiate tumorigenesis.[27] This observation was recently validated and extended in an independent study with a separate cohort of patients.[67]

Recent whole-genome sequencing of human retinoblastomas and their matched germline DNA demonstrated that at least some retinoblastomas have relatively stable diploid genomes with few CNVs or somatic nucleotide variations,[63] and thus genome instability may not be required for retinoblastoma progression. One of the most common misconceptions related to cancer genomics is that tumors with few CNVs have stable genomes and tumors with more CNVs have unstable genomes. Chromosome instability is a dynamic process that cannot be accurately measured at a single time point because it involves the acquisition of sequential chromosomal lesions over time. It is important to distinguish between such dynamic processes that reflect the continuous accumulation of genetic lesions versus more acute genomic events such as multiple chromosome trisomies as seen in hyperdiploid acute lymphoblastic leukemia (ALL), multiple chromosome loss as seen in hypodiploid ALL, and the more recently described process of chromothripsis.[68,69] The best way to directly analyze chromosome instability is to sample the same tumor at multiple time points and perform a comprehensive analysis of the genetic landscape at each time point. Orthotopic xenografts of human retinoblastoma in immunocompromised mouse eyes have proved to be very useful for analysis of chromosome instability in retinoblastoma because the genomic landscape can be analyzed sequentially over time.[63] Clearly this does not preclude the possibility that some retinoblastomas have unstable genomes, but genome instability is not a universal hallmark of *RB1*-deficient retinoblastomas, nor is it required for rapid tumor progression.

In the most recent genomic analysis of retinoblastoma, single nucleotide polymorphism 6.0 analysis was performed on 94 human retinoblastomas and matched normal germline DNAs. These data were used to identify regions of loss of heterozygosity and copy number changes, including whole chromosomes, regional changes, and focal changes (<3 Mb). Specifically, the majority (70%) of retinoblastomas have relatively few (≤10 per tumor) chromosomal, regional, or focal CNVs.[67] No correlation was found between the number of CNVs and the heritable or sporadic form of disease, nor was there any relationship between the type of *RB1* mutation and the number of lesions.[67] A much larger study will be required to determine if more subtle associations exist between the clinicopathologic features of retinoblastoma and the rate of CNVs.

The overall low rate of CNVs was consistent with the paucity of focal recurrent lesions in genes. As reported previously, inactivation of the *RB1* gene and the *BCOR* gene were the most common deletion events, and amplification of the *MYCN* gene was the most common focal recurrent gain.[63] In this most recent study, a new recurrent focal amplification of orthodenticle homeobox 2 *(OTX2)* was discovered in 3% of retinoblastomas. *OTX2* is a homeobox gene that is involved in photoreceptor and retinal pigment epithelium development.[70-73] Retinoblastomas express a variety of rod and cone photoreceptor genes,[38,52] and in future studies, it will be important to determine if OTX2 plays a role in modulating the photoreceptor differentiation program in retinoblastoma.

One of the most important aspects of the study was analysis of the relationship between mutations in *MYCN, BCOR,* and *OTX2* and the mechanism of *RB1* inactivation by sequencing all 27 exons of *RB1* in the cohort.[67] In total, 10 tumors were identified that had no single nucleotide variations or insertions or deletions in the coding region of *RB1*. Whole-genome sequencing on those 10 tumors and their matched normal germline DNA led to the identification of one tumor with a wild-type *RB1* gene and *MYCN* amplification. That tumor sample showed robust RB1 nuclear protein expression, suggesting that retinoblastoma can initiate in the absence of *RB1* mutation. Gene expression array analysis showed that the tumor with wild-type *RB1* was indistinguishable from all other retinoblastomas with *RB1* mutations. Those data confirm a previous report from the Gallie laboratory that a small subset of retinoblastomas (~1% to 2%) have wild-type *RB1*.[27] More importantly this larger more recent genomic analysis also identified three tumors that had focal chromothripsis, disrupting the *RB1* gene and leading to loss of RB1 protein expression. The chromothriptic lesions are not detected by routine genetic analyses because all the exons are present in the genome. This is the first example of chromothripsis in the *RB1* gene in human cancer and the first clear example of chromothripsis as a mechanism for tumor initiation in a well-defined developmental cancer—retinoblastoma. Whole-genome sequencing combined with break-apart fluorescence in situ hybridization analysis of the *RB1* locus and RB1 immunohistochemistry (IHC) can be used to identify this unique subset of retinoblastoma tumors.

Retinoblastoma Preclinical Models

Mouse models of cancer have become increasingly important in the fields of cancer genetics and translational research. The importance of mouse models is particularly true for pediatric cancers because the patient population is relatively small and preclinical models are essential for validating the efficacy of new combinations of chemotherapy before initiating clinical trials in children. In addition, animal models of cancer can provide important new insight into the molecular, cellular, and genetic mechanisms underlying tumor initiation and progression.

One challenge of modeling pediatric cancer in mice is that these tumors initiate in the context of developing tissues that change rapidly, and the cells that give rise to the tumors can display an extraordinary degree of plasticity and heterogeneity. This situation is further complicated by the fact that many tumor suppressor genes and protooncogenes play essential roles in regulating cell-fate specification and differentiation during development. Specifically, the genetic lesions that contribute to tumor initiation and progression may also alter the intrinsic cell-fate specification and differentiation programs in the tumor cells, thereby making it very difficult to infer the cell of origin for that tumor.

Retinoblastoma is a relatively simple tumor that initiates with a common genetic lesion (*RB1* inactivation) and progresses rapidly in children. Moreover many features of retinal development are also conserved across species, making retinoblastoma an ideal tumor for cross-species comparison.

During the past decade a series of knockout mouse models of retinoblastoma have been generated by conditionally inactivating multiple Rb family members in the developing retina.[52,74,75] Knockout mouse models of retinoblastoma have also been valuable for studying the contribution of other tumor suppressor pathways such as the p53 pathway[74] and for testing novel therapeutic agents for the treatment of retinoblastoma.[76,77] In one study six different strains of mice that developed retinoblastoma were analyzed side by side using the same retinal progenitor–specific Cre transgene (*Chx10-Cre*) to inactivate tumor suppressor genes in the developing retina.[52] Histopathologic analysis, gene expression profiling, and morphometric, neuroanatomic, and neurochemical analyses[52] showed that mouse retinoblastomas faithfully recapitulate the molecular and cellular features of human retinoblastomas. However whereas the timing of retinoblastoma initiation was indistinguishable across the six strains, tumor penetrance and the rate of progression varied dramatically.[52] These data raise the possibility that the genetic and epigenetic changes that accompany human retinoblastoma progression may not be faithfully recapitulated in the mouse, despite the remarkable interspecies similarities at the molecular and cellular level.

To more directly assess the similarities and differences across species for retinoblastoma, a recent study analyzed the aneuploidy, CNVs, somatic nucleotide variations, and epigenetic landscape of murine retinoblastoma. Similar to human retinoblastoma, mouse tumors have a low rate of single-nucleotide variations in genes.[78] However mouse retinoblastomas have a higher rate of aneuploidy and regional and focal copy number changes, and this is dependent on the genetic lesions that initiate tumorigenesis in the developing murine retina.[78] In addition the epigenetic landscape in mouse retinoblastoma was significantly different from human tumors, and some pathways that are candidates for molecular targeted therapy for human retinoblastoma such as SYK or myeloid cell leukemia–1 are not deregulated in genetically engineered mouse models (GEMMs). Taken together these data suggest that important differences exist between mouse and human retinoblastomas with respect to the mechanism of tumor progression, and those differences can have significant implications for translational research to test the efficacy of novel therapies for this devastating childhood cancer.

In fact, preclinical testing of combination chemotherapy (etoposide, carboplatin, and vincristine) showed dramatic differences in response between GEMMs and human orthotopic xenografts; virtually all of the GEMMs were cured of their disease, whereas no improvement was seen in progression-free survival or overall survival in the orthotopic xenograft model.[79] It is possible that such species-specific differences could be further amplified when testing molecular targeted therapeutics directed toward processes important for maintaining genomic stability or the epigenetic landscape of retinoblastoma or targeting pathways such as SYK/myeloid cell leukemia–1 that are not deregulated in murine retinoblastoma. A careful assessment of the pathways that are deregulated in murine retinoblastomas is essential to make an accurate evaluation of the efficacy of novel therapeutics in preclinical studies focused on selecting the most promising new drugs for testing in clinical trials.

Understanding the intra- and interspecies differences is paramount when choosing the right model for the study of retinoblastoma. Unlike orthotopic xenograft models, genetic mouse models present the advantage of understanding the developmental processes that support tumor formation arising from a single cell and provide an ideal tool for genetic characterization of the contribution of individual pathways in retinoblastoma progression. On the other hand, orthotopic xenografts from patients faithfully recapitulate the mechanisms by which gene deregulation occurs in the human disease and can be more accurate for testing novel therapeutics. As a result, orthotopic xenografts are an important tool for target identification and target validation during preclinical trials, and GEMMs are important for understanding tumor initiation and progression in the developing retina.

Retinoblastoma Translational Research

Worldwide retinoblastoma is diagnosed in approximately 8000 children each year, including 250 to 300 patients in the United States. In developed countries more than 90% of patients with localized retinoblastoma disease are cured using a combination of chemotherapy, focal therapies, surgery (enucleation), and radiation therapy.[80-85] However many patients in developing countries present with advanced intraocular or metastatic disease. Although mortality is low with aggressive multimodal therapy, partial or full loss of vision occurs in approximately 50% of patients with advanced bilateral retinoblastoma.[86] In addition, significant late effects of therapy occur, including facial deformities and increased incidence of secondary malignancies.[87,88] A vigorous effort is now under way to develop targeted therapies to improve ocular salvage and vision preservation and reduce late effects of therapy without compromising therapeutic outcomes.[63,89]

Major advances have recently been made in understanding the biology of retinoblastoma, including identification of several molecular targets such as the inhibition of the MDM4-p53 interaction, SYK, histone deacetylase (HDAC), and the B-cell lymphoma–2 (BCL2) family of proteins. MDM4 is overexpressed in most human retinoblastomas and has been shown to contribute to tumor formation by suppressing p53. Consequently specific inhibition of the MDM4-p53 interaction represents a promising drug target for retinoblastoma treatment. The small-molecule MDM2/MDM4 antagonist nutlin-3a has been shown to efficiently induce p53-mediated cell death in retinoblastoma cells and mouse models of retinoblastoma.[79] Subsequent characterization of the genetic and epigenetic landscapes of retinoblastoma revealed profound increases in expression of the protooncogene *SYK*. Although *SYK* is not expressed in the normal human retina, it is upregulated in all retinoblastomas analyzed to date.[63] *SYK* is also expressed at high levels in metastatic and posttreatment retinoblastomas (Brennan and Bahrami, unpublished data). Many small-molecule *SYK* inhibitors with diverse physiochemical properties are in development for rheumatoid arthritis and oncology applications, and some of these novel therapeutics may eventually benefit patients with retinoblastoma.[90-93] Moreover, previous studies of *SYK* inhibition have implicated a number of downstream signaling molecules, including the BCL2 family of proteins, as mediators of the *SYK* survival signal.[94] Thus small-molecule BCL2 inhibitors currently in development for other cancers, such as Obatoclax, ABT-737, and TW-37,[95] may also prove to be effective therapeutic agents for retinoblastoma. Retinoblastomas are also highly sensitive to HDAC inhibition, and many HDAC inhibitors are currently in clinical trials.[96]

Retinoblastoma is unique because several well-established routes of drug delivery exist that provide flexibility when considering novel therapeutics. Systemic routes can be used for some drugs but are typically limited by poor penetration across the blood-retinal barrier (BRB) and systemic toxicity concerns.[89] Local ocular delivery routes include topical (transcorneal), periocular (transscleral), intravitreal (direct injection) and intraarterial infusion. However all routes are not amenable to all compounds because of the physiochemical property of the compounds, the effects on normal tissues, and the schedule of drug administration. Some chemotherapy drugs such as topotecan effectively cross the BRB, and equivalent intraocular pharmacokinetic (PK) profiles result from either systemic or local topotecan.[77,97] Topotecan is routinely administered daily for 5 days in children with cancer, providing repeat tumor exposure in an outpatient setting. In contrast carboplatin and nutlin-3a[79,98] cannot be administered systemically because of insufficient penetration of the BRB, and in these cases, subconjunctival injections have been a significantly more effective delivery route. However subconjunctival injections are only performed during examination with use of an anesthetic once every 3 weeks, precluding the opportunity for repeat dosing of the drug. Moreover reports of significant and dose-limiting local ocular toxicities of carboplatin have prevented widespread use of subconjunctival delivery for children with retinoblastoma. These studies highlight the importance of pharmacokinetics and toxicokinetics in drug-specific route selection for intraocular targets.

Because of the young age of the patient population and the relatively rarity of the disease, preclinical testing is a critical component of developing retinoblastoma therapeutics. A standardized approach for evaluating efficacy and safety using mouse genetic models of retinoblastoma and human orthotopic xenograft models has been developed, but the large number of potential compounds, routes, and formulations precludes preclinical testing of all possible combinations. Previous work suggests that, given the unique challenges of drug delivery to the eye, one way to streamline the candidate selection process is to determine which route and formulation achieve optimal PK before conducting preclinical studies. When administered using the routes and formulations that, according to PK studies, achieved target intraocular exposure, topotecan, nutlin-3a, and carboplatin were all efficacious. In contrast, despite promising in vitro cytotoxicity, subconjunctival delivery of a SYK inhibitor failed to provide efficacy in preclinical studies; this failure was related to insufficient exposure. However alternative formulations and routes of local delivery did improve PK compared with systemic delivery; intraocular concentration never reached levels required for cytotoxicity.

In conclusion, effective translational research for retinoblastoma is built on a foundation of outstanding basic research to advance our understanding of the pathways that are deregulated in this devastating childhood cancer. From there, suitable targets for therapy are identified, such as MDM4, HDAC, or SYK, and small molecules that disrupt signaling through those pathways are identified and tested for in vitro cellular effects. Next pharmacokinetic, pharmacodynamic, and toxicokinetic studies are combined with approaches to optimize formulation of the drugs for the different routes of delivery. Finally when suitable exposure is achieved with minimal toxicity, comprehensive preclinical testing using validated preclinical models is performed to compare efficacy of the new combination with current standard of care and other possible novel therapeutic approaches. Variations in schedule and integration with upfront standard of care therapy can also be tested at this stage to achieve an optimal route, dose, and schedule for a new retinoblastoma clinical trial.

GENETIC COUNSELING FOR FAMILIES WITH RETINOBLASTOMA

Retinoblastoma is a unique neoplasm in that the genetic form imparts a predisposition to developing tumor in an autosomal-dominant fashion with almost complete penetrance (85% to 95%).[99] The majority of such children acquire the first mutation as a new germline mutation, with only 15% to 25% having a positive family history. However some families display an inheritance pattern characterized by reduced penetrance and expressivity.[26] These low-penetrance retinoblastoma mutations either cause a reduction in the amount of normal protein produced or result in a partially functional mutant protein.[100] An MDM2 polymorphism has also been shown to modify the clinical penetrance of the RB1 mutation, either by enhancing RB1 haploinsufficiency or by increasing resistance to p53-mediated apoptosis.[101] Also the *RB1* gene mutation can occur at a late stage of embryogenesis, resulting in a variable expression depending on the tissue, causing mosaicisms in 10% to 15% of the patients or their progenitors.[102] In general, however, based on the inheritance pattern and considering the existence of mosaicisms, the following risk estimates can be made,[99] which may be refined on the basis of DNA sequence analysis of the *RB1* gene in the patient with retinoblastoma and his or her offspring or siblings.

1. Risk for offspring of survivors of retinoblastoma:
   a. The risk of retinoblastoma arising in the offspring of survivors of bilateral disease is 45%.
   b. In the case of patients with unilateral disease, investigators have estimated the risk of retinoblastoma overall to be 2.5%. However this estimate includes offspring of survivors of unilateral retinoblastoma who have a positive family history and whose risk is similar to that of bilateral cases—45%. If the family history is negative and genetic screening has not been performed, the actual risk is probably less than 2%.
2. Risk for siblings of patients with retinoblastoma: In the case of siblings of bilaterally affected children whose parents are also affected, the risk of developing retinoblastoma is 45%; if the sibling is unilaterally affected, the risk is 30%. For cases without a family history, the empirically derived risk is 2% for siblings of bilateral cases and 1% for siblings of unilateral cases.

Genetic counseling is of the utmost importance to assist parents in understanding the genetic consequences of each form of retinoblastoma and to estimate the risk in relatives. Counseling is relatively straightforward when a parent is affected, or when the child presents with bilateral disease; these patients all have the heritable form. For children without an affected parent who have only a single tumor, there is always a question about whether they carry the mutated gene. Children with unilateral disease who are older than 2 years at the time of diagnosis are not likely to be gene carriers, but we recommend that all children with retinoblastoma be screened for mutations in *RB1,* regardless of laterality and age at diagnosis. With the refinement in methods of mutational analysis during the past decade, detection rates have increased from 20% to 30%,[103,104] to 70% to 80%,[105,106] to greater than 90% at present.[26] Given the heterogeneity in the site and type of gene defects, no single technology will be sensitive and effective, and a multistep approach must be taken. More than 80% of the mutations can be detected with sequencing of the 27 exons of the *RB1* gene using a quantitative multiplex polymerase chain reaction.[26,105] However 10% to 20% of the defects are due to large deletions,[104,105] and therefore deletion scanning and Southern blotting is required for cases with no detectable mutations by quantitative multiplex polymerase chain reaction. Finally a small proportion of cases (probably less than 5%) may result from gene inactivation by promoter methylation, and therefore screening for constitutional[26,105] methylation should be considered if the other methods do not reveal a mutation. Finally 1% to 2% of retinoblastomas have germline *RB1,* and in these cases *MYCN* amplification and chromothripsis of the *RB1* gene may be the initiating events.[27]

With the recent improvements in the detection rates, genetic testing could be performed in the offspring of retinoblastoma survivors who are known to have the mutated gene (detection of the mutation is relatively easily accomplished if the parental mutation is known), and screening can be tailored appropriately. Even if genetic screening is negative for the mutation, newborn siblings of children with retinoblastoma should be examined periodically until they are about 2 years of age, because inherited retinoblastoma would be extremely rare beyond that age. In the future if the false-negative rate is negligible, one might expect that molecular diagnosis of mutations would lead to earlier treatment and better health outcomes for patients with retinoblastoma, with lower cost than conventional surveillance for children at risk.[26]

PATHOLOGY OF RETINOBLASTOMA

Retinoblastoma arises from the photoreceptor elements of the inner layer of the retina and usually extends into the vitreous cavity as a fleshy nodular mass (endophytic retinoblastoma).[107] Less frequently it extends externally, causing a secondary retinal detachment, in which case there is no localized visible vitreous nodule (exophytic retinoblastoma). Macroscopically retinoblastoma is soft and friable and it tends to outgrow its blood supply, with resulting necrosis and calcification. Because of its friability, dissemination within the vitreous and retina in the form of small, white nodules (seeds) is common. In those cases it may be difficult to distinguish a multicentric primary tumor from a disseminated tumor.

Microscopically the appearance of retinoblastoma depends on the degree of differentiation. Undifferentiated retinoblastoma is composed of small, round, densely packed cells with hypochromatic nuclei and scant cytoplasm. Several degrees of photoreceptor differentiation have been described and are characterized by distinctive arrangements of tumor cells. Homer-Wright rosettes are composed of irregular circlets of tumor cells arranged around a tangle of fibrils with no lumen or internal limiting membrane. They are infrequently seen in retinoblastoma and are most often seen in other neuroblastic tumors such as neuroblastoma and medulloblastoma. Flexner-Wintersteiner rosettes, on the other hand, are specific for retinoblastoma. These structures consist of a cluster of low columnar cells arranged around a central lumen that is bounded by an eosinophilic membrane analogous to the external membrane of the normal retina. The lumen contains an acid mucopolysaccharide similar to that found around normal rods and cones. These rosettes are seen in 70% of tumors. The fleurettes are less often seen. In this case the cells exhibit even more ultrastructural characteristics of photoreceptor differentiation. They are composed of larger cells with abundant eosinophilic cytoplasm arranged in a distinctive fleur de lis pattern. Especially well-differentiated tumors composed almost entirely of fleurettes have been called retinomas or retinocytomas. Ultrastructurally retinoblastoma cells also demonstrate photoreceptor differentiation with the presence of the 9-0 microtubule doublet pattern, abundant cytoplasmic microtubules, synaptic ribbons, and neurosecretory granules.[108,109]

Dissemination of retinoblastoma occurs via several routes. Choroidal invasion provides access to a rich vascular network that serves as a potential route for distant metastases. In advanced cases direct extension occurs through the sclera into the orbit. Retinoblastoma can also invade the iris and the ciliary body and metastasize to the regional lymph nodes. Finally retinoblastoma can extend along the optic nerve, gaining access to the subarachnoid space and intracranial cavity. In cases of disseminated disease, positive cone-rod homeobox (CRX) staining may help differentiate retinoblastoma from other common small, blue, round cell malignancies of childhood.[110] The typical macroscopic and microscopic characteristics of retinoblastoma are depicted in Figure 56-1. Guidelines for processing and evaluation of the enucleated eye have been published.[111]

CLINICAL MANIFESTATIONS OF RETINOBLASTOMA

Retinoblastoma is by definition a tumor of the young child, and the age at presentation correlates with laterality. Patients with bilateral retinoblastoma tend to present at a younger age (usually before 1 year) than do patients with unilateral disease (often in the second or third year of life).[99,112] Half of the cases of retinoblastoma diagnosed during the first year are bilateral, compared with fewer than 10% of cases diagnosed after 1 year of age.[1] It is rare for retinoblastoma to be diagnosed during the first month of life, except in familial cases in which examination has been recommended early; however, regardless of the family history, in more than 90% of neonatal cases, either bilateral disease is present at presentation or asynchronous bilateral retinoblastoma will develop.[107]

In more than half of cases the presenting sign is leukocoria, which occasionally is first noticed after a flash photograph (Fig. 56-2). Strabismus, the second most common presenting sign, usually correlates with macular involvement. Very advanced intraocular tumors may become painful as a result of secondary glaucoma.[112] Other childhood diseases that can present with leukocoria must be considered, such as persistent hyperplastic primary vitreous, retrolental fibrodysplasia, Coats disease, congenital cataracts, toxocariasis, and toxoplasmosis. In some series these nonmalignant conditions account for a significant proportion of enucleated eyes.[113,114] In familial cases, the diagnosis is usually made through screening, although almost 50% of familial cases are diagnosed later in life, when patients present with the typical signs of retinoblastoma, underscoring the importance of genetic counseling.[112]

The successful management of retinoblastoma depends on the ability to detect the disease while it is still intraocular. Disease stage correlates with delay in diagnosis.[115,116] In developing countries, late referrals are strongly associated with orbital and metastatic disease (Fig. 56-2).[116-118] For this reason, eye assessment should be performed in all newborns and at all subsequent health supervision visits by the primary care provider.[119] Eye assessment is encouraged in all newborns and at subsequent health visits. The consensus guidelines by the American Academy of Pediatrics and Bright Futures for Pediatric Preventive Care include health supervision visits at birth and at 3 to 5 weeks of life, at 1, 2, 4, 6, 9, and 12 months during the first year, at 15, 18, and 24 months during the second year, and at 30 months and 3, 4, and 5 years of life. Importantly evaluation of vision and ocular health, including red reflex examination, is a component of each health supervision visit. Mass screening is also being considered, especially where the tumor presents in advanced stages, such as in areas of South America and Asia. Photoscreening is a system by which a photograph is produced by a calibrated camera under prescribed lighting conditions, which shows a red reflex in both pupils. A trained observer can identify ocular abnormalities by recognizing characteristic changes in the photographed pupillary reflex. This technique is fast, efficient, and reproducible, but it is still evolving.[120]

Most patients with bilateral retinoblastoma carry a germline mutation of the *RB1* gene. However a small proportion (5% to 6%) carry a deletion involving the 13q14 locus, which is large enough to be detected by karyotype analysis, either as a deletion or as part of a balanced translocation, most typically t(X;13).[121] In those cases retinoblastoma is part of a more complex syndrome resulting from the loss of additional genetic material. Patients with the 13q deletion syndrome are characterized by typical facial dysmorphic features, subtle skeletal abnormalities, and different degrees of mental retardation and motor impairment.[122-124] Dysmorphic features more consistently found include thick anteverted ear lobes, a high and broad forehead, a prominent philtrum, and a short nose.[122,123] A proportion of patients also

have overlapping fingers and toes, microcephaly, and delayed skeletal maturation. The severity of the deficits correlate with the size of the deletion; normal psychomotor development may be seen in patients in whom the deletion is restricted to the 13q14 band.[122]

Trilateral retinoblastoma refers to the association of bilateral retinoblastoma with an asynchronous intracranial tumor (Fig. 56-3).[125-127] Tumors comprising trilateral retinoblastoma are primitive neuroectodermal tumors (PNETs) exhibiting varying degrees of neuronal or photoreceptor differentiation, suggesting an origin from the germinal layer of primitive cells.[128] This association can occur in 3% to 9% of patients with the heritable form and appears to be more common in familial cases. Until recently the prognosis has been almost uniformly fatal; trilateral retinoblastoma has been the principal cause of death from retinoblastoma during the first decade of life in the United States.[129] The majority of these tumors are pineal region PNETs (pineoblastomas), but in 20% to 25% of cases, the tumors are suprasellar or parasellar. Rare cases of quadrilateral retinoblastoma have been reported, in which bilateral retinoblastoma is associated with both pineal region and suprasellar intracranial primary PNETs.[130] In most cases, the intracranial PNETs in association with retinoblastoma resemble undifferentiated retinoblastomas with the more frequent formation of Homer-Wright rosettes. The median age at diagnosis of trilateral retinoblastoma is 23 to 48 months,[125,126,129,131] and the interval between the diagnosis of bilateral retinoblastoma and the diagnosis of the brain tumor is usually more than 20 months.[127,131] Suprasellar tumors are usually diagnosed earlier,[127] and in 15% to 20% of cases, the intracranial tumor antecedes the diagnosis of retinoblastoma.[126] In recent years with the more widespread use of chemoreduction treatments and the decrease in the use of radiation therapy for patients with bilateral retinoblastoma, the incidence of trilateral retinoblastoma has decreased dramatically.[132,133] However pineal cysts

develop in approximately 5% to 8% of patients with bilateral disease; these cysts appear to be a forme fruste of trilateral retinoblastoma.[133,134,135]

DIAGNOSIS AND EXTENT OF DISEASE EVALUATIONS IN RETINOBLASTOMA

The diagnosis of intraocular retinoblastoma is usually made without pathologic confirmation. An examination with use of an anesthetic with a maximally dilated pupil and scleral indentation is required to examine the entire retina. A careful examination of the iris and the anterior chamber is first performed, and the intraocular pressure is measured. Retinoblastoma usually appears as a mass projecting into the vitreous, although the presence of retinal detachment or vitreous hemorrhage may make its visualization difficult. Endophytic tumors are those that grow inward to the vitreous cavity. Because of its friability, endophytic retinoblastoma may seed the vitreous cavity (Fig. 56-4, *D*). Exophytic retinoblastoma grows into the subretinal space, thus causing progressive retinal detachment and subretinal seeding (Fig. 56-4, *C*). Exophytic tumors frequently resemble Coats disease. Less frequently retinoblastoma can adopt an infiltrative pattern without an obvious mass; this infiltrative pattern appears to be more frequent among older children. A very detailed documentation of the number, location, and size of tumors, the presence of retinal detachment and subretinal fluid, and the presence of vitreous and subretinal seeds must be performed. Wide-angle real-time retinal imaging systems such as RetCam (Clarity Medical Systems, Pleasanton, Calif.) provide a 130-degree field of view and digital recording, facilitating diagnosis and monitoring.

Additional imaging studies that aid in the diagnosis include bidimensional ultrasound, computerized tomography (CT), and magnetic resonance imaging (MRI). These imaging studies are particularly important to evaluate extraocular extension and to differentiate retinoblastoma from other causes of leukocoria. CT is very helpful to detect calcifications, although it is generally avoided to limit radiation exposure, particularly in children with bilateral disease, and MRI is very helpful in considering the differential diagnosis of Coats disease and other inflammatory conditions, along with persistent fetal vasculature of hyperplastic primary vitreous (Fig. 56-3).[136] In the absence of extraocular disease, MRI is not useful in the estimation of microscopic or optic nerve involvement.[137-139]

Evaluation for the presence of metastatic disease also needs to be considered in a subgroup of patients. Metastatic disease occurs in approximately 10% to 15% of patients, and it usually occurs in association with distinct intraocular histologic features, such as massive choroidal and scleral invasion, or with involvement of the iris or ciliary body and optic nerve beyond the lamina cribrosa.[140] In these cases additional staging procedures must be performed, including bone scintigraphy, bone marrow aspirates and biopsies, and lumbar puncture. In as many as one third of high-risk patients, the synthase of ganglioside GD2 messenger ribonucleic acid may be detected in the cerebrospinal fluid by reverse transcriptase-polymerase chain reaction, and it appears to correlate with massive involvement of the optic nerve, the presence of glaucoma at diagnosis, and a high risk of cerebrospinal fluid relapse.[141] In general in the absence of high-risk disease in patients undergoing enucleation, and in patients with intraocular disease who are undergoing ocular salvage therapies, a metastatic workup is usually not necessary. In patients with extraocular disease the use of immunocytology with GD2 or CRX staining may increase the yield for detection of small clumps of metastatic cells.[142,110]

STAGING OF RETINOBLASTOMA

The Reese-Ellsworth (R-E) grouping system has been generally accepted as the standard for intraocular disease. This grouping system was initially designed to predict the outcome after external beam radiation therapy (EBRT). It divides eyes into five groups on the basis of the size, location, and number of lesions and the presence of vitreous seeding (Box 56-1).[143] However developments in the conservative management of intraocular retinoblastoma have made the R-E grouping system less predictable of eye salvage and less helpful in guiding treatment.[85,144] A new staging system (International Classification of Retinoblastoma) has been developed, with the goal of providing a simpler, more user-friendly classification that is more applicable to current therapies. This new system is based on the extent of tumor seeding within the vitreous cavity and subretinal space rather than on tumor size and location, and it seems to be a better predictor of treatment success (Box 56-2; Fig. 56-4).[144,145]

For patients undergoing enucleation, pathologic staging that incorporates other features known to influence the modality of treatment and the prognosis, such as choroidal and scleral involvement, optic nerve extension, and the presence of metastatic disease, is used.

Box 56-1 **Reese-Ellsworth Grouping for Suitability for Treatment of Retinoblastoma by Radiation Therapy**

GROUP I. VERY FAVORABLE

Ia. Solitary tumor smaller than 4 dd at or behind the equator
Ib. Multiple tumors, none larger than 4 dd, all at or behind the equator

GROUP II. FAVORABLE

IIa. Solitary tumor, 4 to 10 dd, at or behind the equator
IIb. Multiple tumors, 4 to 10 dd, at or behind the equator

GROUP III. DOUBTFUL

IIIa. Any lesion anterior to the equator
IIIb. Solitary tumor larger than 10 dd behind the equator

GROUP IV. UNFAVORABLE

Iva. Multiple tumors, some larger than 10 dd
IVb. Any lesion extending anteriorly to the ora serrata

GROUP V. VERY UNFAVORABLE

Va. Massive tumors involving more than half the retina
Vb. Vitreous seeding

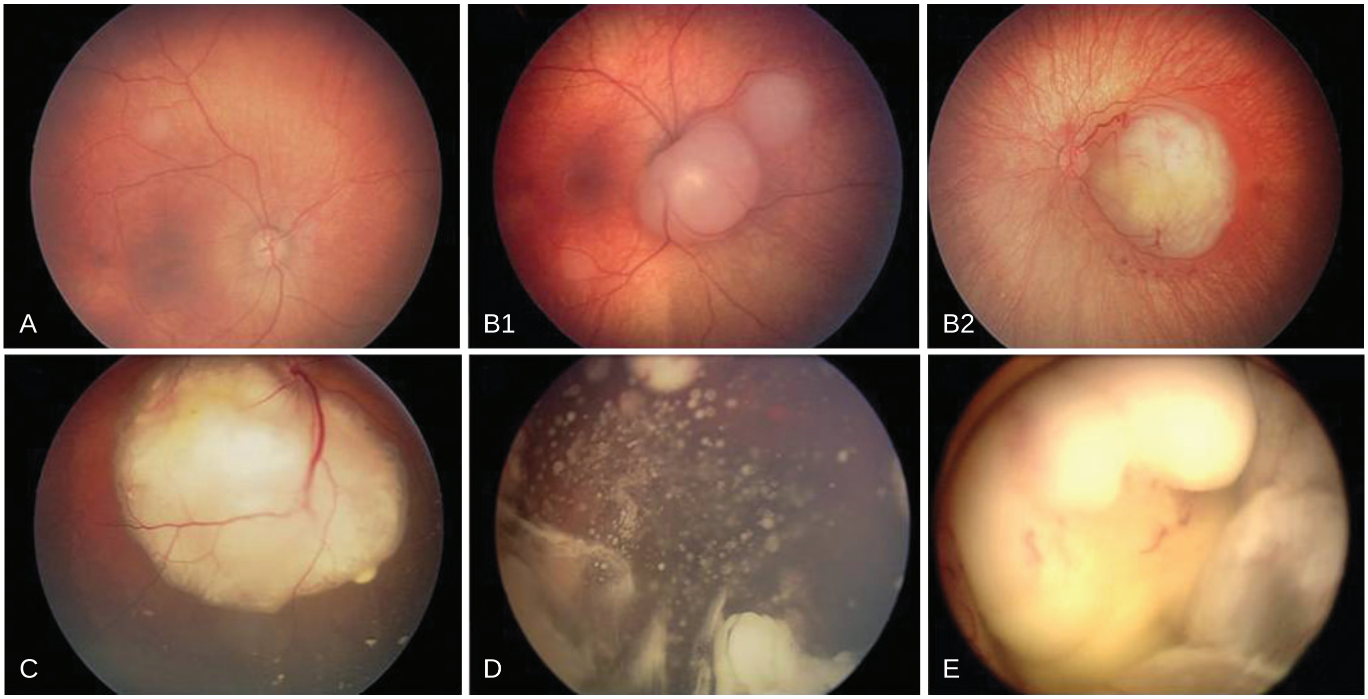

Figure 56-4 International Classification for Intraocular Retinoblastoma. **A,** A small tumor confined to the retina and distant from the foveola and the optic nerve (group A). **B1,** Two small tumors confined to the retina but adjacent to the optic nerve (group B). **B2,** Tumor with a small amount of subretinal fluid and no subretinal seeding (group B). **C,** Exophytic retinoblastoma with subretinal fluid and seeding (group C). **D,** Endophytic retinoblastoma with massive vitreous seeding (group D). **E,** Large retinoblastoma filling more than two thirds of the globe (group E).

Growth and invasion occur as a sequence of events, and extraretinal extension occurs only after the tumor has reached large intraocular dimensions.[146] As part of this process, retinoblastoma extends into the ocular coats (choroid and sclera), the optic nerve, and the anterior segment. Extraocular disease is the next step in this progression; locoregional dissemination occurs by direct extension through the sclera into the orbital contents and preauricular lymph nodes, and extraorbital disease manifests as intracranial dissemination and hematogenous metastases. Different staging systems have been classically used, including the Grabowski-Adamson,[147] the St. Jude Children's Research Hospital,[148] the American Joint Committee on Cancer (AJCC),[149] and the International Retinoblastoma Staging System (IRSS).[150] The IRSS is a newly proposed staging system developed by an international consortium of ophthalmologists and pediatric oncologists that incorporates the most important elements of the older systems (Box 56-3). The IRSS (Box 56-3) and AJCC (Box 56-4) systems appear to be the most reliable for grouping patients according to their risk of extraocular relapse.[151]

Although the clinical significance of extraocular extension is obvious, there is no uniform agreement on the prognostic implications of the different histologic characteristics, resulting in the use of different staging

Box 56-2 **International Classification for Intraocular Retinoblastoma**

GROUP A

SMALL TUMORS AWAY FROM THE FOVEOLA AND DISC

- Tumors ≤3 mm in the greatest dimension confined to the retina, *and*
- Located at least 3 mm from the foveola and 1.5 mm from the optic disc

GROUP B

ALL REMAINING TUMORS CONFINED TO THE RETINA

- All other tumors confined to the retina not in group A
- Subretinal fluid (without subretinal seeding) ≤3 mm from the base of the tumor

GROUP C

LOCAL SUBRETINAL FLUID OR SEEDING

- Local subretinal fluid alone >3 to ≤6 mm from the tumor
- Vitreous seeding or subretinal seeding ≤3 mm from the tumor

GROUP D

DIFFUSE SUBRETINAL FLUID OR SEEDING

- Subretinal fluid alone >6 mm from the tumor
- Vitreous seeding or subretinal seeding >3 mm from the tumor

GROUP E

PRESENCE OF ANY OR MORE OF THESE POOR PROGNOSIS FEATURES

- More than two thirds of the globe is filled with tumor
- Tumor in the anterior segment
- Tumor in or on the ciliary body
- Iris neovascularization
- Neovascular glaucoma
- Opaque media from hemorrhage
- Tumor necrosis with aseptic orbital cellulitis
- Phthisis bulbi

systems. Even in the absence of extraocular disease, a variable risk of developing metastatic disease exists.[152-160] Many studies have attempted to evaluate the risk associated with the different histologic variables. Two thirds of patients have exclusive retinal disease, and invasion of the anterior segment, choroid, and optic nerve occur in variable proportions and combinations in the remaining patients. Extension of tumor into the sclera and across the line of transection of the optic nerve are associated with elevated mortality and by definition are considered to represent extraocular disease.[157,159,160] The question arises when interpreting the other variables, because the risk associated with each variable is confounded by the lack of standardized grading methods and biased by the use of adjuvant chemotherapy.

Optic nerve involvement is common (occurring in 25% to 45% of all cases), but its impact on outcome appears to be limited to the involvement beyond the lamina cribrosa (where the meninges insert) and to the extension up to the transection line.[152,153,159-164] The mortality rates for untreated patients with those features are 40% to 60% and greater than 80%, respectively.[153-156,159,160]

Choroidal involvement is found in up to 40% of patients, although massive invasion occurs in fewer than 10% of cases.[156,158,161,164,165] This distinction is important, because although choroidal invasion might have prognostic implications,[140,152,162,166] its impact appears to be limited to cases with massive replacement by tumor.[158,161] However contrary to optic nerve evaluation, criteria for determining the extent of choroidal disease are more subjective, and the grading of invasion is seldom reported. Consensus criteria for definition of massive or significant choroidal invasion include a maximum diameter (thickness or width) of invasive focus of tumor of 3 mm or more in any diameter and reaching the inner fibers of the sclera. A tumor focus of less than 3 mm and not reaching the sclera is considered focal choroidal invasion.[111]

Evaluating the risk for each histologic variable individually is insufficient; different combinations of simultaneously occurring factors are very frequent.[146,167] When choroidal invasion is present, half the cases will also show optic nerve involvement, whereas optic nerve invasion is uncommon (20%) if the choroid is intact.[152,155,168] Conversely, when the optic nerve is invaded, 30% to 40% of cases will have choroidal replacement (more than 80% if the tumor has spread to the transection line), but significant choroidal invasion is quite rare (less than 20%) if the optic nerve is free of tumor.[152,154,155,167,168] Therefore the risk associated with each histologic variable can only be estimated in the light of its association with others. Most available data support the notion that choroidal invasion alone is not associated with increased risk of extraocular spread, although massive choroidal replacement by tumor may be an exception.[158,161] Similarly retrolaminar optic nerve invasion appears to be of prognostic significance only when there is concomitant significant choroidal invasion,[155,159,165,168,169] but this represents fewer than 20% of cases.[152,155] The significance of other histologic features, such as invasion of the anterior segment or grade of differentiation, remains unclear.[161,162] The presence of extensive tumor necrosis appears to correlate with high-risk histologic features, such as postlaminar optic nerve involvement and choroidal invasion.[170]

Clinical presentation correlates with disease only in cases of advanced intraocular disease; group E eyes, and those presenting with increased intraocular pressure or buphthalmos, have a higher frequency of high-risk histology.[164,171]

PRINCIPLES OF TREATMENT OF RETINOBLASTOMA

Treatment of retinoblastoma aims to save life and preserve useful vision, and thus it needs to be individualized. Factors that need to be considered include laterality of the disease and *RB1* germline status, potential for preserving vision, and intraocular and extraocular staging. For patients presenting with intraocular disease, particularly those with bilateral eye involvement, a conservative approach consisting of tumor reduction with intravenous or ophthalmic artery chemotherapy coupled with aggressive focal therapy may result in high ocular salvage rates. Radiation therapy, one of the most effective treatments in retinoblastoma, is usually reserved for cases of intraocular or extraocular disease progression.

Surgery

Enucleation is indicated for large tumors filling the vitreous for which there is little or no likelihood of restoring vision, and in cases of tumor present in the anterior chamber or in the presence of neovascular glaucoma. This corresponds to group E eyes and a significant proportion of group D eyes; upfront enucleation should be offered to those patients. Enucleation should be performed by an experienced ophthalmologist. The eye must be removed intact, without seeding the malignancy into the orbit and avoiding globe perforation. For optimal staging, a long section (10 to 15 mm) of the optic nerve needs to be removed with the globe. An orbital implant is usually fitted during the same procedure, and the extraocular muscles are attached to it. In the past, orbital

CLINICAL CLASSIFICATION (cTNM)

PRIMARY TUMOR (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumors no more than 2/3 the volume of the eye with no vitreous or subretinal seeding
T1a	No tumor in either eye is greater than 3 mm in largest dimension or located closer than 1.5 mm to the optic nerve or fovea
T1b	At least one tumor is greater than 3 mm in largest dimension or located closer than 1.5 mm to the optic nerve or fovea. No retinal detachment or subretinal fluid beyond 5 mm from the base of the tumor
T1c	At least one tumor is greater than 3 mm in largest dimension or located closer than 1.5 mm to the optic nerve or fovea, with retinal detachment or subretinal fluid beyond 5 mm from the base of the tumor
T2	Tumors no more than 2/3 the volume of the eye with vitreous or subretinal seeding. Can have retinal detachment
T2a	Focal vitreous and/or subretinal seeding of fine aggregates of tumor cells is present, but no large clumps or "snowballs" of tumor cells
T2b	Massive vitreous and/or subretinal seeding is present, defined as diffuse clumps or "snowballs" of tumor cells
T3	Severe intraocular disease
T3a	Tumor fills more than 2/3 of the eye
T3b	One or more complications present, which may include tumor-associated neovascular or angle closure glaucoma, tumor extension into the anterior segment, hyphema, vitreous hemorrhage, or orbital cellulitis
T4	Extraocular disease detected by imaging studies
T4a	Invasion of optic nerve
T4b	Invasion into the orbit
T4c	Intracranial extension not past chiasm
T4d	Intracranial extension past chiasm

REGIONAL LYMPH NODES (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node involvement
N1	Regional lymph node involvement (preauricular, cervical, submandibular)
N2	Distant lymph node involvement

METASTASIS (M)

M0	No metastasis
M1	Systemic metastasis
M1a	Single lesion to sites other than CNS
M1b	Multiple lesions to sites other than CNS
M1c	Prechiasmatic CNS lesion(s)
M1d	Postchiasmatic CNS lesion(s)
M1e	Leptomeningeal and/or CSF involvement

PATHOLOGIC CLASSIFICATION (pTNM)

PRIMARY TUMOR (pT)

pTX	Primary tumor cannot be assessed
pT0	No evidence of primary tumor
pT1	Tumor confined to eye with no optic nerve or choroidal invasion
pT2	Tumor with minimal optic nerve and/or choroidal invasion:
pT2a	Tumor superficially invades optic nerve head but does not extend past lamina cribrosa *or* tumor exhibits focal choroidal invasion
pT2b	Tumor superficially invades the optic nerve head but does not extend past lamina cribrosa *and* exhibits focal choroidal invasion
pT3	Tumor with significant optic nerve and/or choroidal invasion:
pT3a	Tumor invades optic nerve past lamina cribrosa but not to surgical resection line *or* tumor exhibits massive choroidal invasion
pT3b	Tumor invades optic nerve past lamina cribrosa but not to surgical resection line *and* exhibits massive choroidal invasion
pT4	Tumor invades optic nerve to resection line or exhibits extra-ocular extension elsewhere
pT4a	Tumor invades optic nerve to resection line but no extra-ocular extension identified
pT4b	Tumor invades optic nerve to resection line and extra-ocular extension identified

REGIONAL LYMPH NODES (pN)

pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node involvement
pN1	Regional lymph node involvement (preauricular, cervical)
N2	Distant lymph node involvement

METASTASIS (pM)

cM0	No metastasis
pM1	Metastasis to sites other than CNS
pM1a	Single lesion
pM1b	Multiple lesions
pM1c	CNS metastasis
pM1d	Discrete mass(es) without leptomeningeal and/or CSF involvement
pM1e	Leptomeningeal and/or CSF involvement

implants were avoided because it was believed that they would interfere with the palpation of the socket and clinical detection of orbital recurrence. However with improved understanding of the histologic risk factors and the availability of better imaging techniques to detect orbital disease, implants should be placed at the time of the enucleation. Different orbital implants are available, including polymethylmethacrylate, polyethylene, and coralline and bovine hydroxyapatite spheres. A tissue wrap to the implant is placed, which will allow the four rectus muscles to be anatomically reattached, thus providing implant motility with little resistance in the orbit. The size and type of implant are important to stimulate orbital growth. A ceramic false eye is later fitted in the orbital socket. Orbital exenteration is very seldom indicated, although it should considered in cases of tumor recurrence after radiation. For patients presenting with orbital disease, a judicious use of chemotherapy, surgery, and radiation therapy will result in effective tumor control, avoiding the need for orbital exenteration.

Focal Therapies

Focal treatments are used for small tumors (less than 3 to 6 mm) and in combination with chemotherapy.[172] In this setting of a patient undergoing chemotherapy for cytoreduction, focal treatments should be applied to tumors that fail to calcify; it is usually recommended to allow maximal reduction in tumor size with one or two cycles of chemotherapy prior to proceeding with aggressive focal consolidation to minimize the damage to the surrounding retina, particularly when the tumor is close to visually critical structures, such as the fovea and the optic nerve.[173] The focal therapies available to treat retinoblastoma include argon green laser, diode laser, cryotherapy, and brachytherapy. The use of each modality depends on the tumor location and size. Lasers are more commonly used to treat posterior tumors, whereas more anterior tumors are easily accessed with cryotherapy. Brachytherapy is reserved for tumors that cannot be consolidated with either of those two approaches, usually because of their size.[172]

Two wavelengths of light are used to treat retinoblastoma. The argon green laser, with a wavelength of 532 nm, photocoagulates tissue by inducing a temperature in excess of 65°C; it has been traditionally used to treat the retina edge surrounding a tumor in an effort to deprive the tumor of its blood supply and subsequently induce tumor regression, and for the treatment of retinal neovascularization due to radiation therapy.[172,174] Using an indirect ophthalmoscope, a double row of white burns is used to encircle the tumor, and powers of 250 to 350 mW and burn durations of 0.3 to 0.5 seconds are used.[172,175] This technique is limited to tumors measuring no greater than 4.5 mm in base and no greater than 2.5 mm in thickness. Debate exists as to whether the tumor surface should be directly treated for fear of releasing tumor cells into the vitreous. Newer generations of the 532-nm laser permit continuous delivery similar to that of the diode laser; such modalities have led some persons to advocate its use in the treatment of retinoblastoma.[172] If the tumor surface is treated, the desired end point remains a subtle whitening of the treated areas. Laser energy should be kept at the lowest possible level necessary to achieve the desired end point; powers in excess of 500 mW will result in tumor disruption and should be avoided. As with all focal therapies, treatment should be continued until the residual fish-flesh tumor regresses into a flat chorioretinal scar. Typically treatment with lasers is administered every 3 to 4 weeks. The optimal indication for direct treatment with the argon green laser is a residual fish-flesh mass overlying a largely calcified tumor. In such situations, the uptake of the diode laser is unpredictable. With use of the argon green laser, a whitening of the tumor can be seen, ensuring an adequate treatment. The argon laser has both direct and indirect cytotoxic effects. Photocoagulation directly kills tumor cells, and the thermal spread from the laser may have secondary hyperthermic effects that act synergistically with ongoing chemotherapy. Argon laser photocoagulation should not be performed if there is a retinal detachment overlying the tumor.[172]

The diode laser, with a wavelength of 810 nm, was adapted for the treatment of retinoblastoma based on its success in the treatment of choroidal malignant melanoma. The laser energy is readily absorbed by melanin pigment and proved successful in the treatment of small melanocytic tumors.[172] Low-power settings coupled with a large spot size (2 to 3 mm) and prolonged delivery achieved hyperthermia (45°C to 65°C) at subphotocoagulation temperatures. The end result was a sustained penetrant burn with direct cytotoxic effects.[172] The term *transpupillary thermotherapy*, or TTT, was coined to describe this technique.[176,177] The methods of TTT were subsequently adapted to treat retinoblastoma. The infrared laser is focused directly on the tumor surface using either an ophthalmic microscope adapter or a large spot size indirect ophthalmoscope adapter. When using the indirect ophthalmoscope for TTT, it is important to ensure that the correct adapter is being used, because adapters designed for diode photocoagulation will not provide a continuous wavelength delivery necessary for hyperthermia.[172,178] For small tumors the underlying retinal pigment epithelium aids in absorption and transfer of the heat to the tumor. The desired end point is a subtle whitening of the tumor free of hemorrhage. Powers are titrated based on the tumor size and pigmentation of the underlying retinal pigment epithelium but should not exceed 600 mW when there is visible uptake by the surrounding retinal pigment epithelium. Tumors with significant elevation or residual elements that rest on adjacent calcified tumor do not readily whiten with TTT. Prolonged treatment sessions of 5 to 10 minutes using powers of 600 to 800 mW may be needed to achieve a therapeutic effect. Even with such prolonged treatment, a visible change in the tumor may not be seen until follow-up examination 3 to 4 weeks later. If available the argon green laser may provide a more effective treatment.[172] The sequential administration of thermotherapy with carboplatin enhances the antitumor effect by increasing the platinum-DNA adducts, for which reason thermochemotherapy is becoming a very important component in the treatment of intraocular retinoblastoma.[81,83]

Cryotherapy is used for the treatment of small equatorial and peripheral lesions, measuring no more than 3.5 mm in base and no more than 2 mm in thickness.[172,179,180] Cryotherapy is directly cytotoxic, causing cell lysis by disruption of the cell membrane that occurs after the formation of cytoplasmic ice crystals. Nitrous oxide gas is used to deliver a transscleral freeze via a cryoprobe under direct visualization. The lesion to be treated is visualized with an indirect ophthalmoscope, and the scleral underlying the tumor is indented with a cryoprobe. A succession of three freezes with three intervening thaws is applied to the tumor. An “ice ball” should be seen to encompass the tumor and adjacent vitreous with each freeze. Treatment should be limited to the area of the tumor to minimize damage to adjacent normal retina. Multiple tumors may be treated at one examination, but extensive treatments should be avoided. Aggressive cryotherapy may cause serous retinal detachments and iatrogenic retinal breaks. Although each cryotherapy unit may vary, we target a freezing temperature of −70°C during treatment. Treatments should be repeated at 3- to 4-week intervals until the lesion regresses to a flat chorioretinal scar. Posterior tumors can also be treated with cryotherapy. The conjunctiva is opened in the quadrant of the tumor to be treated. The curved cryoprobe is passed along the curvature of the eye and the tumor is indented. Once the tumor has been identified, the triple freeze-thaw is applied. This “cut-down” cryotherapy is usually reserved for recurrent posterior tumors not amenable to laser treatment.[172] Also in addition to its effect on tumor control, cryotherapy contributes to increase the intraocular penetration of chemotherapy agents, presumably through disruption of the blood-vitreous barrier.[181,182] In general local control rates of 70% to 80% can be achieved.[174,180,83] Complications of focal treatments include transient serous retinal detachment, retinal traction and tears, and localized fibrosis.[179]

Chemotherapy

Chemotherapy is indicated in patients with extraocular disease, in the subgroup of patients with enucleated eyes with intraocular disease and high-risk histologic features, and in patients with bilateral disease in conjunction with aggressive focal therapies. Agents with documented efficacy include microtubule inhibitors (vincristine and paclitaxel), platinum compounds (cisplatin and carboplatin), topoisomerase II inhibitors (teniposide and etoposide), alkylating agents (cyclophosphamide and ifosfamide), anthracyclines (doxorubicin and idarubicin), and topoisomerase I inhibitors (topotecan).[183,184] The first clinical experience with chemotherapy in the treatment of retinoblastoma was reported with the use of nitrogen mustard in 1953.[185] Institutional experiences in the management of extraocular retinoblastoma were reported subsequently, usually applying regimens modeled after the treatment regimens for metastatic neuroblastoma.[186,187] Since then the role of chemotherapy has continued to expand, and it is now a main component in the management of intraocular disease.

Ocular Pharmacokinetics

Application of new therapeutic possibilities for cancer treatment involves drug delivery in many forms, but ocular drug delivery is hampered by the barriers protecting the eye. The eye is protected from the xenobiotics of the bloodstream by blood-ocular barriers. The anterior blood-eye barrier (blood-aqueous barrier) is constituted by the endothelial cells in the uvea. This barrier limits access of hydrophilic drugs from plasma into the aqueous humor; however, inflammation may disrupt the integrity of this barrier, causing unlimited drug distribution to the anterior chamber. The posterior blood-eye barrier (BRB) is formed by the neural retina, the retinal pigment epithelium (RPE), and the tight walls of retinal capillaries. The inner border of the neural retina faces the vitreous, and the outer border is next to the RPE. The neural retina is composed of nine layers, and the RPE is composed of a monolayer of polarized cells. The blood supply to the inner two thirds of the retina is from retinal vessels; the retinal endothelial cells have basal lamina, and they are surrounded by pericytes, thus forming tight junctions. The blood supply to the outer third of the retina and the RPE comes from the choroidal circulation. Unlike the retinal capillaries, the vasculature of the choroid has extensive blood flow and leaky walls; drugs easily gain access to the choroid extravascular space, but thereafter distribution into the retina is limited by the RPE and retinal endothelia.[188,189] Lipophilicity, molecular weight, and protein binding (it is believed that only unbound drugs can pass through the BRB) are the main factors for penetration through the barrier. Inflammation and trauma also have important roles in breaking the BRB by disrupting tight junctions, increasing transendothelial vesicles, and increasing pinocytosis.[190] It is possible that a similar phenomenon occurs in retinoblastoma.

Ocular Drug Transporters

The BRB restricts the movements of substances after systemic and periocular administration to the retina. The tight junctions form the penetration barrier to hydrophilic substances, thereby limiting the transfer of compounds both inward (blood to vitreous) and outward (vitreous to blood). The RPE has many important features essential for normal retinal function, such as transport of nutrients and waste products, regulation of ion, and fluid balance. RPE thus expresses many transporters and channels related to these physiologic functions. Among those the RPE and the endothelial cells also express efflux transporters such as P-glycoprotein, multidrug resistance–associated protein–1, –4, and –5, and breast cancer resistance protein. This efflux protein activity restricts movements of certain drugs to the retina. In most cases this is an important protective system for the retina, but it also limits drug delivery to the posterior eye segment.[188] Many antineoplastic agents are known substrates of efflux proteins.

Mechanisms for Transscleral Drug Delivery

Transscleral drug delivery is a potential solution to the need to achieve high intraocular concentrations of chemotherapeutic agents. Traditionally subconjunctival, subtenon, and retrobulbar injections have been used to administer drugs such as steroids and local anesthetic agents. The high permeability of the sclera to macromolecules has revived the interest in this route of drug administration.[191] For transscleral drug delivery, the drug is placed into a periocular space (subconjunctival, subtenon, peribulbar, retrobulbar, or posterior juxtascleral), and it may permeate from the periocular space into the vitreous via the anterior chamber, via a direct penetration pathway across the sclera, or through the systemic circulation. In the anterior chamber route, the drug reaches the aqueous humor either directly across the sclera and ciliary body or indirectly via the tear fluid and cornea, and it subsequently diffuses to the posterior chamber and into the vitreous. In the direct penetration pathway, the drug permeates into the vitreous through the underlying tissues; in the anterior eye, the drug may diffuse through the ciliary body and then to the posterior chamber and vitreous, whereas in the posterior eye, the drug has to permeate across the choroid, retinal pigment epithelium, and neural retina to reach the vitreous. Finally a small proportion of the drug enters the general circulation via conjunctival, episcleral of choroidal vessels and returns into the eye with the systemic blood flow.[189] The relative importance of each route to vitreal drug delivery has been investigated in animal models. The direct penetration pathway is the most important route in the vitreal delivery of most compounds with widely differing physicochemical properties.[191]

The drug must permeate across several tissues, and some of the barriers are different in the anterior and posterior eye. The RPE is the rate-limiting permeation barrier in the retinal delivery of hydrophilic drugs and macromolecules through the transscleral route. Permeability in RPE is determined both by physical-chemical factors (e.g., molecular weight, lipophilicity, and charges) and affinity to active transporters. The transporters may decrease or increase the drug transfer across the RPE depending on the type of transporter (influx or efflux) and its location (vitreal or blood side). The permeating drug also faces active barriers such as the clearance via choriocapillaris blood flow. The choroidal blood flow is higher than in any other tissue (relative to the tissue weight), and choriocapillaris walls contain large fenestrations. Large macromolecules are able to diffuse through the fenestrations in rabbit choriocapillaris. In a rabbit model for administration of triamcinolone acetonide, elimination of the blood flow with cryotherapy did not result in improved penetration of the drug after subtenon administration.[61,192] The orbital and conjunctival vasculature and lymphatics seem to have a larger role in drug clearance than does the choroid. The elimination of conjunctival lymphatic and blood flow by incising a small window in the conjunctiva was more effective in increasing the vitreous concentration than was the elimination of the choroidal blood flow. When considering the orbital clearance, the posterior subtenon location appears to be the best periocular route, because it is closer to the sclera and farther from the orbital vasculature.[193] After periocular injection, the drug must penetrate across the sclera, which is more permeable than the cornea. However for the drug to reach the retina, it must pass across the choroid and RPE (a tighter barrier than the sclera), at which point drugs may be cleared significantly to the bloodstream.[194]

The sclera has a large surface area (16.3 cm^2), and scleral permeability shows no dependence on lipophilicity but dependence on molecular radius. The sclera is composed of collagen and proteoglycan fibers with few protein-binding sites. Drugs permeate through the aqueous intercellular media of the sclera, occupying the pores between the collagen fibers. Pore diameter and intercellular space are important determinants of transscleral drug delivery, particularly for drugs such as large hydrophilic peptides and oligonucleotides. Scleral permeability is affected by an increase in intraocular pressure.[190] Scleral permeability may be enhanced in several ways. Treatment of many ocular diseases incorporates the use of transscleral depots, either as scleral implants (used for antiinflammatory agents) or collagen matrix and fibrin sealants, or the use of microspheres and other nanoparticles.[190,195]

Periocular Chemotherapy in Retinoblastoma

Control of the intraocular tumor burden requires achieving high levels of chemotherapeutic agents in all the intraocular compartments, including the vitreous, the subretinal space, and the ocular coats. Although it is effective systemic administration of chemotherapy is limited by the blood-ocular barriers previously described. In recent years methods to increase the intraocular concentrations of chemotherapeutic agents have been extensively investigated, and periocular administration of carboplatin has been incorporated into most regimens for the treatment of advanced intraocular retinoblastoma. In the transgenic murine retinoblastoma treated with intravitreous injections of carboplatin, inhibition of tumor growth occurs in a dose-dependent manner,[196] thus suggesting that higher intraocular levels of chemotherapy would be desirable. In this retinoblastoma model, subconjunctival administration of carboplatin resulted in tumor control in a dose-dependent manner,[197] suggesting good intraocular penetration of this agent when given periocularly. Pharmacokinetic studies performed in the rabbit eye have validated this method.[198] Mendelsohn and colleagues[199] compared the intraocular concentrations of agents after local or systemic administration in primates. Intravenous carboplatin was given at the standard dose used in humans (18.7 mg/kg), and systemic and intraocular pharmacokinetics were compared with peribulbar and episcleral injections of 10 mg of carboplatin. The intravenous administration resulted in higher levels in the aqueous humor than did peribulbar or episcleral injections. However vitreous levels were significantly higher when carboplatin was administered periocularly. Importantly systemic absorption after periocular administration was minimal; plasma levels of carboplatin were 3% of those achieved after intravenous administration. In the same study no etoposide was detected in the aqueous or vitreous humor when given systemically. Etoposide is a protein-bound drug, and it likely stays in the plasma and thus has limited penetration. Studies in the mouse model have also shown little intravitreal penetration of etoposide when given intravenously. The vitreous/plasma ratios when measured as area under the curve concentrations were 0.59 for carboplatin and 0.07 for etoposide.[76] However these models may not recapitulate the natural history of retinoblastoma because the blood-vitreous barrier is likely disrupted by tumor. In fact intraocular carboplatin concentrations in the human eye with retinoblastoma are higher after intravenous administration than what the primate eye model shows; levels in the vitreous are much higher than what the animal studies would predict and are similar to levels measured in unaffected animals when the drug is given after cryotherapy.[200] The periocular route has also been explored in animal models for topotecan[97,201] and for new investigational agents such as SYK and MDM4 inhibitors.[63,79]

Given the promising preclinical data, periocular administration of carboplatin has been progressively incorporated into the clinical practice. Patients tolerate the administration of 2 mL of the 10 mg/mL solution, although acute orbital toxicity is significant. In the only phase II study reported, responses were seen in three of the five eyes with vitreous disease and in two of the five eyes with retinal tumors.[202] The role of this form of administration in the management of retinoblastoma is still being evaluated. Patients with advanced intraocular disease (particularly those with massive vitreous or subretinal seeding) are candidates to receive up to three doses of periocular carboplatin concomitantly with systemic chemotherapy to maximize intraocular levels of the agent. However great caution should be exerted if periocular carboplatin is administered; acute toxicities (e.g., periorbital edema and inflammation) and long-term toxicities (e.g., orbital fat necrosis, soft tissue and muscle fibrosis, and optic neuritis) are common.[203,204] Although periocular carboplatin has a very limited role as a single agent, it may lead to long-term disease control when combined with other treatment modalities (Box 56-4).[205] Topotecan has also been used via periocular administration, although its intraocular penetration may be lower[97,201] and its potential role in therapy may be more limited.[206] In the animal model periocular administration of topotecan reached potentially active levels of its active lactone moiety without significant toxicity.[97] However systemic absorption was significant. A recently completed phase I study has documented the feasibility of administering 2 mg of topotecan periocularly, although no significant responses were seen.[160]

Although effective in increasing intraocular levels, subconjunctival administration of carboplatin or topotecan in aqueous media has many limitations. Most of the drug delivered is dispensed quickly throughout the subconjunctival space and surrounding orbit, thus exposing extraocular tissues to high transient concentrations of the drugs and potential toxicities. Methods for improving periocular delivery while minimizing toxicity include the use of a collagen matrix or fibrin sealants. Studies have shown that carboplatin may enhance fibrin clot formation.[207] One benefit of the sealant is that the anhydrous form of carboplatin can be overloaded beyond its solubility limit to provide higher levels of drug for extended periods. The scleral drug exposure is maximized, extending the duration of therapeutically significant intraocular drug penetration, and decreasing the need for repeated periocular injections.[208] However in the animal models, as the intraocular levels increase, so does the risk of retinal toxicity.[196,208,209]

Intravitreal and Intraarterial Chemotherapy for Intraocular Retinoblastoma

Administration of chemotherapy drugs directly into the tumor vasculature is a common practice in oncology. A small, localized tumor such as retinoblastoma would be an excellent candidate for such an approach. Japanese investigators have pioneered the administration of intravitreal and intraarterial melphalan for patients with advanced or recurrent intraocular retinoblastoma.[210,211] Preclinical data suggest that retinoblastoma is very sensitive to melphalan and that there is a synergistic effect with thermotherapy[212] and with other agents such as topotecan.[213] Direct delivery to the ocular vasculature has been limited by the technical difficulties in the cannulation of the retinal artery. Kaneko and Suzuki[210] initially reported the feasibility of injecting melphalan into the ipsilateral carotid artery, with documented efficacy. The technique was later perfected by Suzuki and colleagues[211] and Mohri[214] using a balloon catheter that allowed for selective injection into the ophthalmic artery. More recently Abramson and colleagues[215] reported a variation of this technique that includes a direct cannulation of the ophthalmic artery using a microcatheter (supraselective). Successful catheterization and delivery of chemotherapy can be achieved in 98% of cases,[216,217] although in 16% of patients an alternative vascular route is required—often the orbital branch of the middle meningeal artery.[218] This approach has also been documented as being feasible as tandem therapy in patients with bilateral disease.[219]

Although melphalan has remained the most commonly used agent and the most effective agent, it is often combined with topotecan or carboplatin when responses are suboptimal or the intraocular disease is very advanced.[216,217,220-223] The doses of the chemotherapeutic agents are determined by patient age (and ocular volume) and by the angioanatomy; doses reported to result in a significant antitumor effect and limited toxicity are 2.7 to 7.5 mg for melphalan, 0.3 to 0.6 mg for topotecan, and 25 to 50 mg for carboplatin.[216,220,221,223,224] In pigs, the infusion of 7 mg of melphalan or 1 mg of topotecan to the ophthalmic artery results in peak vitreous levels higher than the inhibitory concentration of 50%, and with limited systemic exposure.[213,225] In children a large variability of systemic exposure occurs, and patients receiving tandem administrations of melphalan have a higher risk of the development of neutropenia, which correlates with plasma levels.[213]

Patients typically receive one to six (median, three) intraarterial administrations of chemotherapy including melphalan alone or in combination, and responses are usually seen immediately after the first administration. For patients with treatment-naive eyes, the 2-year radiation-free ocular survival rate is 80% to 90%.[216,220,223] Similar outcomes are also being reported with single-agent carboplatin and in combination with topotecan.[221] Outcome correlates with the intraocular burden; patients with early intraocular disease (group B and C eyes) have an excellent outcome and may be treated with single-agent therapy.[221,222] Eyes with significant vitreous or subretinal seeding have a worse outcome, with radiation-free survival rates of 80% for eyes with subretinal seeding and 65% for eyes with vitreous seeding.[226] For patients with very advanced intraocular disease, an alternative is the use of systemic chemotherapy followed by consolidation with intraarterial melphalan.[227] The presence of massive retinal detachment is not a contraindication to intraarterial chemotherapy; studies have shown that this approach promotes retinal reattachment and may result in ocular salvage rates in excess of 85%.[228] Ocular salvage rates when intraarterial chemotherapy administration is used as salvage for patients with recurrent or progressive disease are consistently lower, with globe survival rates of 50% to 60%.[216,217,223,226] However the use of a more intensive three-drug regimen with melphalan, topotecan, and carboplatin in patients whose disease has progressed after undergoing standard systemic and focal therapies has been reported to result in radiation-free ocular salvage rates of 75% at 2 years.[224]

Patients with bilateral disease can receive tandem administrations.[219] In those circumstances patients are at a higher risk of systemic toxicity as a result of melphalan exposure,[213] and single-agent carboplatin may be used to treat the eye with less advanced disease during the tandem procedure.[229] For neonates and very young infants for whom the cannulization of the ophthalmic artery is not feasible, a "bridge" treatment with single-agent systemic carboplatin until the baby is 3 months old or weighs 6 kg followed by consolidation with intraarterial chemotherapy has been shown to be very effective, with 1-year radiation-free ocular survival of 95%.[230]

Direct administration of high doses of chemotherapy to a sensitive organ such as the eye of a young child is not devoid of complications. In the nonhuman primate model, treatment with three cycles of melphalan or carboplatin results in a significant inflammatory response, with leukostasis and retinal arteriole occlusion with ultrastructural changes in the endothelial cells and surrounding pericytes. Eyes also show nerve fiber infarcts and optic nerve hemorrhage and leukostasis, central retinal artery thrombosis, choroidal inflammation, and birefringent intravascular foreign bodies.[231] Similar histopathologic evidence of vasculopathy is seen in enucleated eyes of children with retinoblastoma after intraarterial chemotherapy.[232] Clinically a transient chorioretinal ischemia has been documented during the procedure, the impact of which is not fully understood.[233,234] However approximately 15% of the eyes show a long-term sectorial choroidal atrophy, and 15% have delayed vitreous hemorrhage leading to enucleation.[222,235] The impact of the intraocular vascular changes on vision has not been fully assessed because of the young age of the first cohorts of patients treated. The majority of patients do not have substantial electroretinographic changes,[236] and preservation of central vision has been reported.[237] However in patients with heavily pretreated eyes, intensive intraarterial chemotherapy may result in worsening of retinal function.[224]

Acute and usually transient adverse events include mild eye edema, blepharoptosis, and orbital congestion with temporary dysmotility.[221,222,238] Systemic effects are minimal; grade III neutropenia develops in only 10% of patients,[216] although this proportion is higher in children with bilateral disease who undergo tandem therapy.[213] Major vascular complications are very rare; no strokes or significant acute neurologic events have been reported when the procedure is performed at a state of the art treatment center.[211,216,217] However stenosis of the ophthalmic artery and occlusion of the retinal artery have been documented.[238] The risk of thrombosis is significantly increased in children with thrombophilia.[239]

One additional risk associated with intraarterial chemotherapy is the exposure to ionizing radiation during fluoroscopy. In very experienced hands, the mean fluoroscopy time per procedure is 7 minutes.[240] Radiation doses per procedure can be as high as 191 mGy to the affected eye and 35 mGy to the contralateral eye,[241] although doses as low as 1 mGy per procedure have been reported by the center with the most experience in performing the procedure.[240] After multiple procedures, cumulative doses can reach 0.1 to 0.2 Gy, which can be cataractogenic and potentially carcinogenic in this susceptible population.[241] Long-term outcome data reported by Japanese investigators seem to indicate that no increase occurs in the incidence of second malignancies[211]; however, longer follow-up will be required to fully ascertain the risks associated with the procedure.

To achieve the maximum concentrations of chemotherapy close to the tumor and in the vitreous, investigators have attempted direct intravitreal delivery. This approach was pioneered by Swedish investigators in the 1960s.[242,243] Thiotepa was the agent selected in those initial studies, and repeated injections of 1 to 1.5 mg were administered, often in conjunction with EBRT. Regressions were obtained, but long-term control of the intraocular disease was generally not possible. This approach was rekindled by Seregard et al.[244] in three patients with bilateral disease with recurrent retinoblastoma in a single remaining eye. Patients received repeated intravitreal injections of thiotepa, followed by vitrectomy and weekly injections, for a total cumulative dose of 10 to 14 mg of thiotepa; no obvious clinical responses were observed.

Direct administration of melphalan into the vitreous is a promising approach for patients with vitreous disease. Clinical responses in patients with progressive retinoblastoma were obtained with use of intravitreal melphalan followed by hyperthermia,[210] and more recent data seem to indicate that intravitreal chemotherapy may have a role in the management of patients with progressive vitreous disease.[245,246] This approach is currently being explored in combination with systemic chemotherapy for patients with advanced intraocular disease.

Radiotherapy

Retinoblastoma is a very radiosensitive tumor. Radiotherapy in combination with focal treatments can provide excellent tumor control.[247,248,249] However because radiation therapy increases the risk of second malignancies, contemporary management of intraocular retinoblastoma is designed to avoid or delay its use. The role of irradiation is mainly as salvage management for eyes that have failed to respond to chemotherapy and focal treatments, usually because of progression of vitreous and subretinal seeding.[250] Because most patients with intraocular retinoblastoma who undergo radiotherapy have multifocal disease, the entire retinal surface needs to be irradiated to a uniform dose. Several techniques can be used, usually through lateral or anterior fields.[247-249] Recommended total doses are 40 to 45 Gy, in 180 to 200 cGy fractions, although doses of 36 Gy and even lower may be effective in conjunction with other techniques.[82,251-253] Radioactive plaque technique is useful when treating localized tumors, both because the procedure time is short and because a high dose of irradiation is delivered to the areas of interest while minimizing irradiation effects in extraocular structures.

Episcleral Plaque Brachytherapy

Indications for plaque therapy include solitary tumors with a diameter ranging between 6 and 15 mm, tumor thickness of 10 mm or less, and location of the lesion more than 3 mm from the optic disc or fovea.[250] Since the early use of cobalt-60 plaques in the 1950s, the field has evolved to the more common use of iodine-125, iridium-192, and ruthenium-106.[254-258] In combination with appropriate use of chemotherapy and focal consolidation, brachytherapy can be very effective, even in the presence of focal vitreous seeding overlying the tumor.[250,259]

The most commonly used radioisotope is ^{125}iodine, a low-energy γ-ray emitter (27 to 35 keV; half-life, 60 days) that is readily available in encapsulated form, allowing custom fabrication of gold plaques of varying sizes.[254] ^{125}Iodine seeds are loaded within the wells of the plaque to achieve the dose and distribution desired based on the size and location of the tumor; lesions of up to 10 to 12 mm in height and 10 to 15 mm in diameter can be treated using this approach. ^{192}Iridium and ^{106}ruthenium are alternative isotopes of higher energy (295 to 612vkeV and 3.5 MeV, respectively) and longer half-life (74 and 374 days, respectively), which makes dosimetry calculations and safety measures more complex. The dose is prescribed to reach the tumor apex and overlying localized vitreous seeds if present. For ^{125}iodine the target dose is usually 40 Gy at the apex at 40 to –80 cGy per hour; the dose at the tumor base may approximate 120 Gy. Tumor control using this approach may be close to 80%. In approximately 25% of the eyes, long-term complications may occur, including nonproliferative retinopathy, papillopathy, and nonproliferative maculopathy.[254,260] Similar results are achieved with ^{106}ruthenium.[255]

External Beam Radiation Therapy

EBRT is commonly used as consolidation therapy in conjunction with chemotherapy for intraocular retinoblastoma when the disease is not responding well to conservative management, usually because of the presence of vitreous or subretinal seeding or progression of the retinal tumors, and in the management of extraocular disease.[250] Traditionally the opposed "D" fields have been used to treat bilateral retinoblastoma, with the isocenter placed 2 to 3 mm behind the lens; with this approach, aimed at sparing the lens, the retina anterior to the equator may be relatively underdosed.[261,262] Currently the use of conformal and intensity-modulated radiation therapy (IMRTs) can provide coverage of the entire retina and vitreous cavity while limiting the dose to the lacrimal gland and soft tissues and orbital bones.[262,263] The standard EBRT dose is 40 to 45 Gy, delivered in 180 to 200 cGy fractions; doses higher than 45 Gy do not seem to be associated with an increased benefit.[261] One study also showed the potential role of low-dose (26 Gy) EBRT to consolidate advanced intraocular retinoblastoma upon completion of chemotherapy, in the absence of disease progression.[253] IMRT may be superior to three-dimensional (3D) conformal radiation therapy and conventional two-dimensional irradiation in terms of the dose delivered to normal orbital and extraorbital tissues.[264] However although increasing the conformity of the treatment results in a sharp decline of the dose-volume curve at the higher doses, this gain still comes at the expense of increasing the volume of normal tissue that receives the lowest doses. Even with optimal IMRT planning, 50% of the orbit receives 50% of the prescribed dose.[250] The use of fractionated stereotactic radiation therapy may allow for a significant decrease in the orbital volume exposed.[265] Proton beam therapy allows for exquisite dosimetry, thus providing a theoretic advantage in sparing radiation exposure to orbital tissues.[263,266] A proton beam has exquisite stopping power and may produce essentially no lateral scatter, and thus protons can be used to control tumors at any depth without the entrance and exit doses associated with photon beam irradiation that are responsible for the complications associated with radiation therapy in patients with retinoblastoma.[266] In a study comparing protons with conformal therapy, electron therapy, and IMRT, protons had the best orbital bone-sparing dose distribution. Only 10% of the bone exceeded 5 Gy, compared with 25% for 3D–conformal radiation therapy electrons, 69% for IMRT, 41% for a single 3D lateral beam, 51% for a 3D anterolateral beam with a lens block, and 65% for a 3D anterolateral beam without a lens block.[250,266] Very importantly preliminary long-term data seem to indicate that the cumulative incidence of second malignancies in the irradiated field is significantly lower with protons when compared with standard photon therapy.[267]

Radiation therapy is indicated for extraocular retinoblastoma and after enucleation when high-risk features are present (e.g., transscleral involvement and involvement of the cut end of the optic nerve). The target volume is the orbit and may extend to include regional sites and lymph nodes based on clinical and imaging evidence of tumor extension. The dose typically used for treatment of the orbit or regional extraocular sites is 45 Gy. Radiation therapy may be indicated for patients with metastatic disease based on response to chemotherapy. In most treatment protocols, patients with hematogenous metastases or CNS involvement who achieve a complete response to induction chemotherapy do not undergo irradiation; however, patients with an incomplete response usually undergo irradiation at the completion of therapy, which often includes consolidation with high-dose chemotherapy and autologous hematopoietic stem-cell rescue. This sequence is also recommended for patients who require craniospinal irradiation. Based on age older patients who require craniospinal irradiation should receive 36 Gy to the neuraxis and 45 Gy to residual disease. Younger patients should receive at least 23.4 Gy to the neuraxis. Evidence suggests that clinically defined disease has limited microscopic tumor infiltration so that the clinical target volume surrounding the clinically identifiable residual tumor (gross tumor volume) may be as small as 5 mm.[250]

TREATMENT OF INTRAOCULAR RETINOBLASTOMA

Treatment of retinoblastoma is tailored to the intraocular and extraocular disease burden, disease laterality and germline status, and potential for vision (Fig. 56-5).

Unilateral Retinoblastoma

In the absence of extraocular disease, enucleation alone is curative for 85% to 90% of children with unilateral retinoblastoma.[113,161,165,268] The outcome for patients with unilateral disease that has been enucleated is excellent, with good functional results and minimal long-term effects.[269] However in view of the success in the treatment of bilateral intraocular disease with systemic or intraarterial chemoreduction and focal treatments, more patients

are considered candidates for ocular preservation treatments. This is particularly important in very young children in whom metachronous bilateral disease may develop. Using the standard three-drug regimen (vincristine, carboplatin, and etoposide) and aggressive focal consolidation, more than two thirds of patients with unilateral disease do not respond to therapy and ultimately require either enucleation or radiation therapy.[270] Therefore the use of upfront systemic chemotherapy in this group of patients with unilateral disease needs to be

considered very judiciously and only in cases with low intraocular disease and when focal consolidation is available. Preenucleation chemotherapy results in downstaging with underestimation of extraretinal and extraocular disease, leading to an increased risk of metastatic spread.[271] However patients presenting with group E eyes and buphthalmos, in whom enucleation might be associated with surgical risks, may benefit from preenucleation chemotherapy; in these cases, given the inability to perform proper histologic risk evaluation, patients should be considered to have high-risk disease and be treated accordingly with postenucleation chemotherapy.[164,171]

With the advent of intraarterial chemotherapy, many patients with groups B, C, and D disease are now good candidates for ocular salvage, and long-term eye preservation may be achieved in more than 75% of cases (Box 56-4, Table 56-1, and Fig. 56-5).[216]

For patients undergoing upfront enucleation, a careful histologic evaluation is needed to assess high-risk disease. Adjuvant treatment is indicated in cases with transscleral invasion and in patients with positive tumor at the transection line of the optic nerve (see the discussion in the "Treatment of Extraocular Retinoblastoma" section). Adjuvant treatment for the remaining patients with intraocular disease is more debatable. In the absence of randomized studies, available information would suggest that the use of adjuvant chemotherapy may be beneficial for the selected group of patients with higher risk of extraocular dissemination, which includes involvement of the anterior chamber, ciliary body, or iris, massive infiltration (>3 mm) of the choroid, retrolaminar optic nerve infiltration, or focal choroidal disease in combination with any degree of nonretrolaminar optic nerve involvement (Table 56-2 and Fig. 56-5).[146,156,157-159,161,165,167,272] Adjuvant chemotherapy is not indicated for patients with isolated prelaminar involvement[156,251] or isolated focal choroidal involvement.[158,161,165,251,268] Different chemotherapy regimens have been proposed. Six-month treatment with vincristine, cyclophosphamide, and doxorubicin; vincristine, carboplatin, and etoposide; or a hybrid with alternating courses of both regimens appears to be effective (Table 56-2). Idarubicin is also an effective agent in persons with retinoblastoma and can be substituted for doxorubicin.[273] Radiation therapy is not indicated in these cases.

Bilateral Retinoblastoma

In patients with germline mutation of the *RB1* gene, multiple, bilateral retinoblastomas develop at an earlier age, and these patients are at risk of development of new tumors until the completion of retinal differentiation.[87] In the past treatment for patients with bilateral retinoblastoma has been enucleation of eyes with advanced intraocular disease and no visual potential, and the use of EBRT for the remaining eyes. However, several complications are associated with radiation therapy. Irradiation of the orbit during a period of rapid growth results in a major decrease in orbital volume, resulting in midfacial deformities.[274,275] More importantly however is the greatly increased risk for the development of a sarcoma within the radiation therapy field, compared with the underlying increased risk of secondary neoplasms in these predisposed persons. This risk may be age related and decreases as irradiation is delayed.[276] These concerns have resulted in the development of new and more conservative approaches. The treatment of patients with bilateral retinoblastoma now incorporates upfront chemotherapy, which is intended to achieve maximum chemoreduction of the intraocular tumor burden early in the treatment, followed by aggressive focal therapies (Fig. 56-5). Chemoreduction coupled with intensive use of sequential focal therapies (e.g., cryotherapy, laser photocoagulation, thermotherapy, and brachytherapy) has resulted in an increase in the eye salvage rates and in a decrease (and delay) in the use of radiation therapy. Intraocular retinoblastoma is extremely chemosensitive, and disease progression during treatment is rarely seen. Noticeable responses are seen in more than 90% of the eyes; these responses are maximum after two cycles, and tumor regression after subsequent cycles is less pronounced (Fig. 56-6).[134,277,278] However chemotherapy alone can only save fewer than 10% of

the eyes.[134] Macular tumors are more sensitive to chemotherapy, probably because of the richer vascular supply that maximizes exposure to chemotherapy. Up to two thirds of macular tumors can be controlled with chemotherapy alone,[23,279] and with the addition of thermotherapy, this proportion may increase to greater than 80%.[23,24,279,280] Chemoreduction coupled with intensive use of sequential focal therapies (e.g., cryotherapy, laser photocoagulation, thermotherapy, and brachytherapy) has resulted in an increase in eye salvage rates and in the decrease (and delay) in the use of radiation therapy.

Different chemotherapy combinations are used, although the best results are achieved with a combination of vincristine, carboplatin, and etoposide (or teniposide).[80,83,281-283] An alternative chemotherapy regimen includes the addition of cyclosporin to the three-drug regimen.[284] The rationale for the use of cyclosporin originates from the documentation of the presence of the P-glycoprotein efflux pump in a significant proportion of retinoblastomas, an expression that appears to correlate with treatment failure.[285] The concurrent administration of cyclosporin could potentially abrogate the efflux of drugs from the cancer cell. However the expression of P-glycoprotein does not always seem to predict response,[286] and cyclosporin adds toxicity. For patients with early intraocular stages (R-E groups I to III or International group B), a less intensive regimen with vincristine and carboplatin alone appears to be effective (Box 56-4 and Figs. 56-5 and 56-6).[134,287]

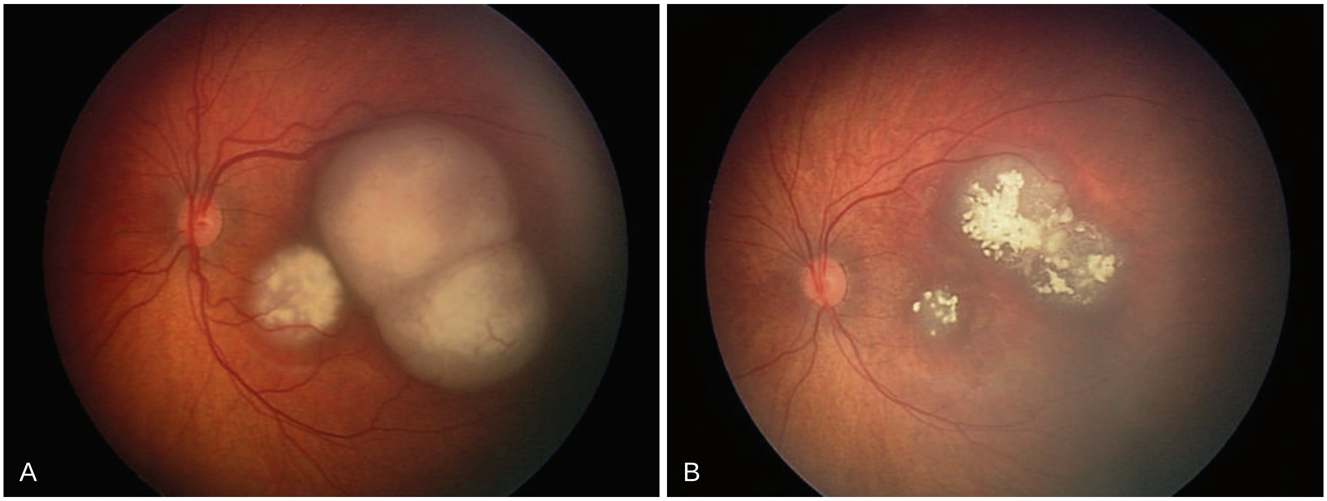

Figure 56-6 Response of a group B retinoblastoma (**A**) to two courses of vincristine and carboplatin (**B**).

Salvage rates for eyes classified as R-E groups I to III approaches 100% with use of these techniques. For patients with advanced intraocular tumors (International groups C and D), ocular salvage rates are not better than 50% to 70% when systemic chemoreduction is used, and EBRT is usually required.[281] However the use of radiation therapy is usually delayed for several months, which allows for better orbital growth and a decrease in the risk of second malignancies. A major proportion of failures occur because of progression of tumor in the vitreous, or as subretinal implants, two areas of difficult access for antineoplastic agents.[80] For these patients, if systemic chemotherapy is used, the addition of periocular carboplatin may be beneficial.[205]

Thus the treatment of patients with advanced intraocular disease (R-E groups IV and V or International groups C and D) remains a major challenge. Although randomized studies have not been performed, compared with radiation therapy and focal treatments alone, chemoreduction does not seem to improve overall ocular salvage significantly for patients with very advanced intraocular disease.[247-249] Chemotherapy intensification appears to correlate with outcome, and better results are obtained with protocols that include at least six courses of vincristine, etoposide, and carboplatin.[281,288,289] Central retinal tumors usually respond better to chemotherapy than tumors in the peripheral retina,[290] but large central tumors may be associated with subretinal seeds, which ultimately may cause treatment failure.[291] Despite the addition of aggressive sequential focal therapies, globe retention is still no better than 50% for patients with group D eyes, and most patients eventually require irradiation. A major proportion of failures occur because of progression of tumor in the vitreous or as subretinal implants, two areas of difficult access for antineoplastic agents.[80] Radiation therapy appears to be the only valid alternative for these patients, and with the incorporation of lower doses of irradiation (26 Gy) early in the treatment, in a situation of minimal disease, before disease progression occurs, ocular salvage rates for International group D eyes may improve.[253]

New agents with better intraocular penetration are under investigation. Topotecan, a topoisomerase-I inhibitor with well-documented efficacy against pediatric tumors, is a promising alternative. Studies performed in the animal model have shown that topotecan has excellent intraocular penetration and antitumor effect.[76] In a phase II study using an upfront window of vincristine and topotecan in patients with advanced bilateral disease, responses were documented in 90% of the patients.[292]

Direct administration of chemotherapy drugs into the ophthalmic artery to maximize drug exposures is a very effective approach and has become the standard of care at many centers, particularly for children with advanced bilateral disease, with ocular survival rates in excess of 80% (as previously discussed).

New Tumor Formation during Treatment with Chemotherapy

In the natural history of patients with germline *RB1* mutation, new tumors continue to form after diagnosis. It is not clear whether the use of chemotherapy may alter this process. Several authors have evaluated the impact of primary systemic chemotherapy on the rate of new tumor formation in patients with hereditary retinoblastoma. For patients receiving treatment with the standard two- or three-drug regimens that include six to eight cycles of chemotherapy, the cumulative incidence of new tumors after the start of chemotherapy is 10% to 24%,[293,294] although higher incidences have also been reported.[295] However most new tumors develop after chemotherapy is discontinued.[134,294] The incidence of new tumors is higher if a regimen of shorter chemotherapy duration is used or only focal treatments are administered.[296-298] Younger age at diagnosis, a family history of retinoblastoma, and lower grouping at diagnosis are factors that significantly increase the likelihood of new tumor formation.[293-295] These risk factors are intrinsically tied together; patients with a family history are more likely to be screened early and be diagnosed at a younger age, early in the natural history of the disease. Importantly the majority of the new tumors after the start of chemotherapy develop in the equatorial or peripheral retina, and fewer than 20% of the tumors form in the macula.[293] This tumor distribution is likely tied to retinal development rather than to the use of chemotherapy, but it is possible that small tumors in the richly vascularized central retina are effectively treated with chemotherapy before they become visible. New tumors may still retain sensitivity to the drugs used, because they likely represent new somatic mutations that occur after the start of treatment. With the recent implementation of intraarterial chemotherapy as primary treatment for patients with bilateral disease, a similar preventive phenomenon has been observed.[299] All in all these data seem to suggest that small tumors undetectable by ophthalmoscopy may be present at diagnosis that can be effectively treated before becoming apparent.

TREATMENT OF EXTRAOCULAR RETINOBLASTOMA

Extraocular dissemination of retinoblastoma bears a close relationship with the socioeconomic conditions that result in delayed diagnosis and treatment. In Europe and the United States, fewer than 5% of patients present with extraocular disease,[152,300,301] in contrast to 12% to 20% in South America,[268,302] 25% to 40% in Mexico and India,[118,303,304] and more than 50% in less developed countries.[305]

Four patterns of extraocular disease have been recognized: (1) locoregional dissemination, including orbital disease, tumor extending to the cut end of the optic nerve, and lymphatic spread to the preauricular lymph nodes; (2) CNS dissemination; (3) metastatic retinoblastoma; and (4) trilateral retinoblastoma (Figs. 56-2 and 56-3).

Orbital and Locoregional Retinoblastoma

Orbital retinoblastoma occurs as a result of progression of the tumor through the emissary vessels and sclera. For this reason, scleral disease is considered to be extraocular and should be treated as such. Orbital retinoblastoma is isolated in 60% to 70% of cases; lymphatic, hematogenous, and CNS metastases occur in the remaining patients.[306] Treatment should include systemic chemotherapy and radiation therapy; with this approach, 60% to 85% of patients can be cured. Because most recurrences occur in the CNS, regimens using drugs with well-documented CNS penetration are recommended. Different chemotherapy regimens have proven to be effective, including vincristine, cyclophosphamide, and doxorubicin, platinum- and epipodophyllotoxin-based regimens, or a combination of both.[307,308,309-311] For patients with macroscopic orbital disease, it is recommended that surgery be delayed until response to chemotherapy has been obtained (usually with two or three courses of treatment). Enucleation should then be performed, and an additional four to six courses of chemotherapy should be administered. Local control should then be consolidated with orbital irradiation (4000 to 4500 cGy). Using this approach, orbital exenteration is not indicated.[312,313] Similar management should be followed for patients with scleral disease, including radiation therapy, although good outcomes without irradiation have also been reported.[302] Patients with isolated involvement of the optic nerve at the transection level should also receive similar systemic treatment, and irradiation should include the entire orbit (3600 cGy) with a 1000 cGy boost to the chiasm (for a total of 4600 cGy). Also because metastases in parameningeal bones have been associated with intracranial dissemination,[307] irradiation fields should be adjusted carefully. The preauricular and cervical lymph nodes should be explored carefully, because 20% of patients with orbital retinoblastoma have lymphatic metastases.[306] Lymphatic dissemination does not carry a worse prognosis, provided that the involved lymph nodes are also irradiated.[301,312,314] Patients with spontaneous or accidental ocular perforation and patients with intraocular surgery for unsuspected retinoblastoma should be considered to have orbital disease by definition and treated accordingly.

Central Nervous System Disease

Intracranial dissemination occurs by direct extension through the optic nerve, and its prognosis is dismal.[308,315,316] Treatment for these patients should include platinum-based intensive systemic chemotherapy and CNS-directed therapy. Although traditionally intrathecal methotrexate (with or without cytosine arabinoside) has been used, no preclinical or clinical evidence exists to support its use.[317] Other intrathecal agents with documented effect against retinoblastoma include topotecan[76,292,318] and thiotepa.[314,319] However no evidence indicates that their use can have an impact on outcome. Although the use of irradiation in these patients is controversial, responses have been observed with craniospinal irradiation, with a dose of 2500 cGy to 3500 cGy to the entire craniospinal axis, and a boost (1000 cGy) to sites of measurable disease.[307,311,312,314,315] Therapeutic intensification with high-dose, marrow-ablative chemotherapy and autologous hematopoietic progenitor cell rescue has been explored,[307] but its role is not yet clear. Despite the intensity of the treatment and the documented responses of the intracranial disease,[316] most patients succumb to their disease, and reports of survivors are anecdotal.[307,309]

Trilateral Retinoblastoma

The prognosis for patients with trilateral retinoblastoma is very poor; most patients die of disseminated neuroaxis disease in less than 9 months.[125,127,131] The rare survivors are usually those diagnosed with screening imaging and treated with intensive chemotherapy with or without craniospinal irradiation.[67,131] Pineal primary neuroectodermal tumors (PNETs; pineoblastoma) occurring in patients without retinoblastoma are also associated with a poor prognosis in younger patients. However with an appropriately aggressive multimodal approach, these patients can be cured. PNETs are chemosensitive tumors, and they appear to have a steep dose-response curve for alkylating agents. Studies in older patients with pineoblastoma have recently shown that a treatment with complete resection and intensive alkylator- and cisplatin-based therapy, followed by craniospinal irradiation (3600 cGy with a boost to the pineal gland to 5900 cGy) and consolidation with high-dose, myeloablative chemotherapy and autologous hematopoietic progenitor cell rescue, may produce survival rates in more than two thirds of patients.[320] It is therefore possible that similar treatment guidelines could be used for trilateral retinoblastoma. However one must consider the serious long-term toxicities of such doses of irradiation in the very young child. Therefore current strategies are directed toward avoiding irradiation and instead using intensive chemotherapy followed by consolidation with myeloablative chemotherapy and autologous hematopoietic progenitor cell rescue, an approach similar to those being used in the treatment of brain tumors in infants. With use of the Head Start regimen, which takes this approach, improved outcomes have been reported in young children who have supratentorial PNETs, including pineoblastomas.[321]

Because of the poor prognosis of trilateral retinoblastoma, screening neuroimaging is a common practice. One fourth of the cases in the literature correspond to cases found during screening.[131] Given the short interval between the diagnosis of retinoblastoma and the occurrence of trilateral retinoblastoma, routine screening might detect the majority of cases within 2 years.[131] Although it is not clear whether early diagnosis can have an impact on survival,[322,323] it is usually recommended that neuroimaging be performed every 6 months until 5 years of age.[127,131,323,324]

(Extracranial) Metastatic Retinoblastoma

Hematogenous metastases may develop in the bones, bone marrow, and, less frequently, in the liver.[302,308,311,312,315,325,326] Although long-term survivors treated with conventional chemotherapy have been reported,[326] these cures should be considered anecdotal; metastatic retinoblastoma is not curable with conventional chemotherapy.[302,312] In recent years, however, small series of patients have shown that metastatic retinoblastoma can be cured with use of high-dose, marrow-ablative chemotherapy and autologous hematopoietic progenitor cell rescue (Table 56-3).[307,308,311,315,325,327,328] The approach is similar to that used with metastatic neuroblastoma; patients receive short and intensive induction regimens that usually contain alkylating agents, anthracyclines, etoposide, and platinum

TABLE 56-3 Recommended Chemotherapy Regimen for Metastatic Retinoblastoma

		DOSES		
Phase	**Drugs**	**<36 months**	**>36 months**	**Days**
Induction (4 cycles)	VCR	0.05 mg/kg	1.5 mg/m^2	1, 8, 15
	CDDP	3.5 mg/kg	105 mg/m^2	1
	CYC	65 mg/kg	1950 mg/m^2	2, 3
	ETO	4 mg/kg	120 mg/m^2	2, 3
Consolidation	CBP	AUC 7 (maximum 16.7 mg/kg)	AUC 7 (maximum 500 mg/m^2)	−8, −7, −6
	TT	10 mg/kg	300 mg/m^2	−5, −4, −3
	ETO	8.3 mg/kg	250 mg/m^2	−5, −4, −3

compounds, and consolidation is then performed with marrow-ablative chemotherapy and autologous hematopoietic cell rescue. With use of this approach, the outcome appears to be excellent. As with any "megatherapy" consolidation, the agents selected may be important. In general recurrences are intracranial, and for this reason, agents with proven efficacy in intracranial retinoblastoma should be used. In this regard the combination of carboplatin and etoposide has been shown to be effective against CNS disease,[316] and for this reason it should be part of the regimen. In one of the largest series, seven patients underwent consolidation with the CARBOPEC combination (i.e., carboplatin, 1250 to 1750 mg/m^2; etoposide, 1750 mg/m^2; and cyclophosphamide, 6.4 g/m^2). Five of these patients were cured, and the regimen failed in two patients because of CNS relapse. In two other series a thiotepa-based consolidation regimen has been used (i.e., thiotepa, 900 mg/m^2; etoposide, 750 to 1200 mg/m^2; and carboplatin, 1500 mg/m^2). A strong rationale exists for using thiotepa: retinoblastoma is responsive to alkylating agents such as thiotepa, a group of agents for which dose escalation is shown to overcome resistance. Furthermore thiotepa has excellent CNS penetration.[308,315,329] An interesting observation is that patients with distant bone metastases (i.e., outside the orbit and skull) that show good response to induction chemotherapy may not require radiation therapy when they are treated with marrow-ablative chemotherapy.[307,327]

LONG-TERM EFFECTS OF RETINOBLASTOMA AND ITS TREATMENT

Retinoblastoma is a cancer of the very young, and patients are very susceptible to the long-term effects that the disease and the treatments administered may have with regard to organ development and function. More importantly patients with bilateral retinoblastoma are born with a germline mutation of the *RB1* gene, probably the most potent tumor suppressor gene, and are at risk of the development of cancers throughout their lives; in this regard, retinoblastoma may be just the beginning.

Second Malignancies

The cumulative incidence of second cancers in patients with germline mutations of the *RB1* gene increases steadily with age, to up to 30% to 60% at 40 to 50 years of age, although more recent studies estimate a considerably lower risk.[87,330-333] Second malignancies are responsible for an excess risk of mortality in survivors of bilateral disease;[334] up to 50% of the deaths of survivors are due to second cancers.[333] The type of mutation, whether de novo or inherited, appears to influence the risk of second cancers—patients with a family history of the disease have a higher cumulative incidence of second neoplasms when compared with survivors of bilateral retinoblastoma who do not have a family history of the disease.[335] Patients with nonhereditary retinoblastoma are not at increased risk. Most information on second malignancies in retinoblastoma survivors is derived from the prospective follow-up of a cohort of 1601 survivors of retinoblastoma who were diagnosed between 1914 and 1984 at institutions in Boston and New York. The sequential updated analyses of this cohort have provided (and continue to provide) the most reliable description of cancer risk in this population.[87,335-337]

In the most recent analysis, the median follow-up for patients with hereditary and nonhereditary retinoblastoma was 25.2 years and 29.5 years, respectively.[87] The standardized incidence ratio (SIR) in these studies was calculated as the ratio of the observed number of cancers to the expected number from the Connecticut Tumor Registry. The incidence of second cancers was significantly elevated in survivors of hereditary retinoblastoma (SIR, 19 vs. 1.2 in patients with nonhereditary retinoblastoma), and almost any neoplasm has been described in this population[87,338]; similar data have been reported using population-based registries.[333] For hereditary retinoblastoma, the greatest risk (SIR >100) was for neoplasms of bone, connective, and soft tissue, eye and orbit, and nasal cavities. An increased risk (SIR >10) was also noted for pineoblastoma, melanoma, CNS malignancies, and neoplasms of the buccal cavity and corpus uteri. The lowest risk (SIR <10) was seen for neoplasms of the lung, breast, and colon (Table 56-4).

The cumulative incidence of a second neoplasm after 30 years from diagnosis of retinoblastoma is greater than 30%.[87,330,331,333,338] Reports differ on the risk, and cumulative incidences in excess of 50% have been reported.[331,338] The more accurate data probably derive from the Boston–New York cohort, which illustrates the changes in cancer

TABLE 56-4 Risk and Type of New Cancers in 963 Survivors of Hereditary Retinoblastoma

Cancer Site	Observed (%)	SIR (95% CI)
All sites	260 (100)	19 (16-21)
Bone	75 (28.8)	360 (283-451)
Soft tissue	34 (13)	122 (84-170)
Nasal cavities	32 (12.3)	1111 (760-1569)
Melanoma	29 (11.1)	28 (18-40)
Eye and orbit	17 (6.5)	266 (155-426)
Brain	10 (3.8)	13.6 (6.5-25)
Breast	10 (3.8)	3.96 (1.9-7.3)
Corpus uteri	7 (2.7)	20 (8.0-41)
Buccal cavity	7 (2.7)	20 (8.2-42)
Lung	5 (1.9)	5.94 (1.9-14)
Pineoblastoma	5 (1.9)	90.8 (29-212)
Colon	3 (1.1)	6.28 (1.3-18)
Hodgkin lymphoma	3 (1.1)	3.4 (0.7-10)
Bladder	2 (0.7)	6.15 (0.7-22)
Thyroid	2 (0.7)	3.34 (0.4-12)
Leukemia	2 (0.7)	2.25 (0.3-8.1)

Modified from Kleinerman RA, Tucker MA, Tarone RE, et al: Risk of new cancers after radiotherapy in long-term survivors of retinoblastoma: an extended follow-up. J Clin Oncol *23:2272–2279, 2005.*

risk estimates with longer follow-up. The cumulative incidence of second cancers at 50 years in survivors of hereditary retinoblastoma was estimated to be 51% in the analysis reported by Wong et al.[331] in 1997. This figure decreased to 36% in the analysis of the same cohort reported by Kleinerman et al.[87] in 2005, probably reflecting the lower doses of scatter radiation received by patients treated in more recent eras. Although patients have a lifetime risk of developing additional malignancies, the second malignancy usually occurs in the first decades after the diagnosis of retinoblastoma. The median age at diagnosis of a second neoplasm is 15 to 17 years.[276,331] However survivors of retinoblastoma continue to have an increased risk of second malignancy–associated death throughout their life.[333,337] Furthermore survivors of a second neoplasm appear to have an increased risk of developing a third and a fourth malignancy, which occur at shorter intervals. The cumulative incidence of a third neoplasm is 22% at 10 years from the time of diagnosis of the second cancer, and it occurs at a median of 5.8 years.[339]

Radiation therapy plays a major role in the risk of second neoplasms in patients with hereditary retinoblastoma. The second tumorigenic event ("second hit") is usually chromosomal in nature, often as a result of mitotic recombination errors.[100,340] This second hit is very sensitive to environmental factors such as ionizing radiation, thus explaining the increased risk of radiation-induced malignancies in survivors of retinoblastoma.[341] Radiation results in a significant increase in the incidence of second cancers in patients with hereditary disease; the cumulative probability of developing a second malignancy is 38% in patients who have been treated with radiation versus 21% in patients who have not been treated with radiation.[87] The greatest risk (SIR >100) is for neoplasms of bone, soft tissues, nasal cavities, and orbits, and for pineoblastoma. The risk of second cancer appears to correlate as well with timing of radiation; children receiving radiation therapy during their first year may have a higher risk of developing a second cancer.[276,337] However the need for earlier radiation may also be an indication of a biologically and clinically more aggressive disease. Changes in radiation techniques over the years are having an impact on cancer risk. As shown in the cohort reported by Kleinerman and colleagues,[87] the use of orthovoltage prior to 1960 was associated with a higher risk of second malignancies than radiation techniques used in subsequent decades; the cumulative incidence of second cancers at 40 years was 32.9% and 26.3%, respectively. With the evolving treatment approaches for intraocular retinoblastoma, which may decrease the overall need for external beam radiation, and the development of newer radiation techniques, such as conformal, intensity-modulated, and proton-beam radiation, it is likely that a further decrease in cancer risk will be observed. In a cohort of British retinoblastoma survivors born before 1950, prior to the routine use of radiation therapy, fewer than 15% of second tumors were sarcomas, highlighting the important role of radiation therapy in the development of those malignancies.[338] Population-based studies have shown a significant decline in the use of radiation therapy during the past decades, from 30.5% of patients in the 1980s to less than 3% after 1999.[333] This change in practice is likely to lead to a further decline in the risk of second cancers in this population.

Traditionally an excess risk has been attributed solely to the use of radiation therapy; the added risk of the use of chemotherapy is not fully understood. In survivors of childhood cancer, an increased risk of second malignancies has been documented, particularly osteosarcoma, which is associated with the combined use of chemotherapy and radiation therapy.[342] A similar phenomenon may occur in retinoblastoma survivors, and the most recent analyses suggest a synergistic effect in carcinogenic risk with the use of chemotherapy. The overall risk of cancer for persons with hereditary retinoblastoma who received radiation and chemotherapy was 25, compared with 19 for persons who received only radiation. Most of this difference was accounted for by the higher risk noted for osteosarcomas; the SIR was 539 for combined treatment and 302 for radiation only.[87]

Sarcomas of bone and soft tissues account for more than 40% of all second neoplasms, followed by neoplasms of the nasal cavities and melanoma (Table 56-4).[87,331] Sarcomas in general and osteosarcoma in particular are cancers of the young retinoblastoma survivor; 76% of all cancers in the irradiated patients occurring at less than 25 years are sarcomas versus 33%

in nonirradiated patients. Conversely 76% of cancers diagnosed at less than 25 years of age are sarcomas, whereas sarcomas represent fewer than 50% of cancers in older patients; in irradiated patients not treated with radiation, the proportion was 33% in persons younger than 25 years and 8% in persons older than 25 years.[87,338]

The role of imaging screening for the early detection of second malignancies has not been fully addressed. One study using whole-body MRI concluded that although this approach had good specificity, its sensitivity was low (66.7%).[343] However age- and disease-specific screening methods may need to be evaluated.

Osteosarcoma

Osteosarcoma as a second malignancy is often associated with retinoblastoma. In the general population only 7% of osteosarcomas follow other malignancies, and almost half of these cases occur in retinoblastoma survivors.[344] Similarly although multifocal osteosarcoma accounts for only 4% of all osteosarcomas, 25% of those occur in retinoblastoma survivors.[345] Osteosarcoma is the most common malignancy in survivors of retinoblastoma, both in the irradiated and the nonirradiated areas, and account for 25% to 40% of all second malignancies.[87,276,337,346-348] One half to two thirds of osteosarcomas occur in the irradiated fields of the skull and face,[87,276,346-348] one third of tumors develop in the extremities, and fewer than 10% develop in the trunk.[87] The SIR is 360; it is higher in irradiated fields (SIR 406), but it is still significantly increased in nonirradiated fields (SIR 69). Osteosarcoma occurring in patients with retinoblastoma who have been treated with radiation therapy accounts for 30% of all osteosarcomas of the head and neck.[349]

The clinical presentation is similar to that of conventional osteosarcoma, and the clinical behavior does not seem to be different; fewer than 20% of the cases are metastatic.[350] Osteosarcomas occur in young patients, both in irradiated and nonirradiated fields, usually peaking during the adolescent years.[276,346,350] However osteosarcomas that occur during the first decade of life are usually in the irradiated fields.[350] With appropriate multidisciplinary treatment, secondary osteosarcoma occurring in retinoblastoma survivors is curable.[351,352] However a major limitation is the common occurrence in the head and neck, which are sites where local control is challenging.[347-349]

Ewing sarcoma, although rare, has also been described in retinoblastoma survivors. It accounts for 15% to 25% of all bone tumors, almost always occurring outside the radiation field.[330,348] Ewing sarcoma in retinoblastoma survivors accounts for approximately 16% of cases of Ewing sarcoma that occur as a second malignancy.[353]

Soft Tissue Sarcomas

Soft tissue sarcomas are the second most common malignancy in retinoblastoma survivors, with an SIR of 122, and they account for approximately 10% to 15% of all second malignancies.[337,354,355,356] Soft tissue sarcomas are closely associated with the use of radiation; the SIR is much higher in irradiated fields (140) than in nonirradiated fields (23). In the Boston–New York cohort, the cumulative risk for soft tissue sarcomas at 50 years after radiation therapy was 13.1%.[354,356] Approximately 10% of all secondary sarcomas in children surviving cancer occur in retinoblastoma survivors.[355]

As with osteosarcoma, most soft tissue sarcomas occur in the irradiated fields; sarcomas of the head and face account for 70% of the cases, with the remaining being in the trunk (20%) and limbs (<5%).[276,346-348,354,356] A very characteristic spectrum of histologies has been described (Table 56-5). Leiomyosarcoma is the most common subtype, accounting for approximately one third of the cases, followed by fibrosarcoma, malignant fibrous histiocytoma, rhabdomyosarcoma, nonspecified sarcomas, and liposarcoma. When compared with the normal population, SIR is significantly elevated for leiomyosarcoma (390), fibrosarcoma (398), and rhabdomyosarcoma (279), but it is also higher for malignant fibrous histiocytoma (100) and liposarcoma (99).[356] A correlation exists between radiation exposure and histologic subtype; fibrosarcoma, rhabdomyosarcoma, malignant fibrous histiocytoma, and nonspecified subtypes almost always occur

TABLE 56-5 Risk and Type of Soft Tissue Sarcomas in 963 Survivors of Hereditary Retinoblastoma

	TREATMENT					
	All Treatments		Radiation		No Radiation	
Histology	Observed (%)	SIR (95% CI)	Observed	SIR (95% CI)	Observed	SIR (95% CI)
Total	69 (100)	184 (143-233)	66	212 (164-270)	3	47 (9.4-137)
Soft tissue sarcoma NOS	10 (14.5)	96 (46-177)	10	115 (55-211)	0	0.0 (0.0-218)
Fibrosarcoma	13 (18.8)	398 (211-681)	13	475 (253-813)	0	0.0 (0.0-691)
Malignant fibrous histiocytoma	12 (17.4)	100 (52-175)	11	110 (55-197)	1	51 (0.66-284)
Liposarcoma	3 (4.3)	99 (20-286)	3	120 (24-351)	0	0.0 (0.0-329)
Leiomyosarcoma	23 (33.3)	390 (247-585)	22	476 (298-720)	1	78 (1.0-436)
Rhabdomyosarcoma	8 (11.6)	279 (120-551)	7	281 (112-578)	1	271 (3.5-1510)

Modified from Kleinerman RA, Tucker MA, Abramson DH, et al: Risk of soft tissue sarcomas by individual subtype in survivors of hereditary retinoblastoma. J Natl Cancer Inst *99:24–31, 2007.*

CI, Confidence interval; *NOS,* not otherwise specified; *SIR,* standard incidence ratio.

in the irradiated fields. Conversely leiomyosarcoma and liposarcoma commonly arise in the nonirradiated fields. Although secondary sarcomas in childhood cancer survivors are associated with increasing doses of anthracyclines or alkylators,[357] the use of chemotherapy does not appear to increase the risk of soft tissue sarcomas in retinoblastoma survivors; however the combined use of radiation and chemotherapy appears to increase the risk for leiomyosarcoma when compared with radiation alone.[356]

Soft tissue sarcomas are a malignancy of the young survivor, and more than half of the tumors are diagnosed in the first 30 years after retinoblastoma diagnosis.[276,346,356] Fibrosarcoma, rhabdomyosarcoma, rhabdomyosarcoma, and malignant fibrous histiocytoma predominantly occur 10 to 20 years from retinoblastoma diagnosis, whereas nonspecified sarcomas occur across all time intervals. An exception to the rule is leiomyosarcoma, which more commonly (78%) occurs after 30 years from retinoblastoma diagnosis, and typically outside the irradiated fields; the SIR for this subtype after 30 years is 435.[28] Very common locations for leiomyosarcoma are the uterus and bladder,[330,337,354,356,358,359] and these tumors may also occur as a radiation-induced malignancy in the paranasal sinuses.[352]

The liposarcoma risk also increases with age.[356] Alteration of the *RB1* gene has been demonstrated in both lipomas and liposarcomas. An interesting observation is the increased incidence of lipomas in survivors of hereditary retinoblastoma. Lipomas were present in 3.6% of patients with hereditary retinoblastoma, compared with only 0.6% in patients with sporadic disease.[360] The incidence of a second neoplasm appears to be higher in patients with lipomas; 30% of patients with lipoma experienced a second malignant neoplasm, compared with 12% of patients without lipoma. These data suggest that the presence of lipomas could be a clinical marker of susceptibility to second neoplasms.[360]

Sarcoma risk and location do not seem to differ by sex, except for leiomyosarcomas. In males, 64% of primaries were in the face, whereas for females, 58% of tumors were in the pelvic area, highlighting the relevance of uterine primary tumors.[356]

Skin Cancers

Skin cancers account for 16% to 19% of all second cancers in survivors of hereditary retinoblastoma, and they occur both inside and outside the irradiated fields, usually within the first three decades of life.[276,330,337,354] The highest risk is for melanoma, but basal cell and squamous cell carcinomas are also common. The SIR for melanoma is 28 in the radiation field and 15 outside the irradiated areas. The risk of developing melanoma is higher in survivors with a family history, compared with persons with de novo mutations.[335] Skin cancer also accounts for approximately one third of all third tumors.[276]

Lung Cancer and Other Common Cancers of Adulthood

In recent years with improvements in treatment that have resulted in longer survival rates, it has become apparent that patients with hereditary retinoblastoma are also at risk of developing epithelial cancers late in adulthood.[337,338] The SIR is elevated for lung, breast, colon, buccal cavity, bladder, and corpus uteri cancers (see Table 56-4).[354] Lung cancer appears to be one of the most common second neoplasms that occur in adulthood, which is not surprising because somatic mutations of the *RB1* gene are known to contribute to the development of lung cancer.[332,361] Compared with the general population, hereditary retinoblastoma survivors have a higher mortality from lung cancer and all other epithelial cancers combined (standard mortality ratio 7.01 and 3.29, respectively).[338] Rather than being epithelial, most bladder and uterine cancers (and a large proportion of colon neoplasms) are probably leiomyosarcomas.[354,356] An increased incidence of breast cancer occurs in patients who have been treated with radiation therapy, but this increased risk is similar for patients with hereditary and nonhereditary retinoblastoma; the dose to the breast from scatter radiation is approximately 0.4 Gy. New reported excess risks include carcinomas of the salivary glands and tongue; low doses of radiation (<5 Gy) have been associated with secondary salivary cancers.[354] It is possible that most of the excess cancer risks might be preventable by limiting exposure to agents that damage the DNA, such as tobacco and ultraviolet light.

Hematologic Malignancies

Patients with hereditary retinoblastoma have a slightly increased risk of developing hematologic malignancies, with an SIR of 2.25 (and an SIR of 1.27 in nonhereditary cases).[354] The use of etoposide and other topoisomerase-II inhibitors such as anthracyclines may add an additional risk to this patient population.[362] However the cumulative doses of those agents are relatively low, and it is therefore assumed that the risk of treatment-related leukemia is minimal. Therapy-related acute myeloid leukemia after the treatment of retinoblastoma has been reported, although its occurrence does not appear to be higher than in other patients receiving etoposide.[363,364]

Trilateral Retinoblastoma

Trilateral retinoblastoma refers to the association of bilateral retinoblastoma with an asynchronous intracranial tumor (Fig. 56-3).[126,129,131] The SIR for trilateral retinoblastoma is 90.8, and it seems to be associated with the use of radiation therapy (SIR is 0 in patients who have not been treated with radiation therapy). Tumors comprising trilateral retinoblastoma are PNETs that exhibit varying degrees of neuronal or photoreceptor differentiation, suggesting an origin from the germinal layer of primitive cells.[128] This association can occur in 3% to 9% of patients with the genetic form and appears to be more common in familial cases. The prognosis is almost uniformly fatal. Trilateral retinoblastoma was the principal cause of death from retinoblastoma during the first decade of life in the United States.[129] The majority of these tumors are pineoblastomas, but in 20% to 25% of the cases, the tumors are suprasellar or parasellar. The association of bilateral retinoblastoma with a tumor in the pineal gland and a fourth primary tumor of suprasellar location is called “quadrilateral retinoblastoma.”

In most cases trilateral retinoblastoma resembles undifferentiated retinoblastomas, with the more frequent formation of Homer-Wright rosettes. The median age at diagnosis of trilateral retinoblastoma is 23 to 48 months,[125,126,129,131] and the interval between the diagnosis of bilateral retinoblastoma and the diagnosis of the brain tumor is usually more than 20 months.[127,131] Suprasellar tumors are usually diagnosed earlier,[42,127] and in 15% to 20% of the cases, the intracranial tumor antecedes the diagnosis of retinoblastoma.[126] In recent years with the more widespread use of chemoreduction treatments for patients with bilateral retinoblastoma and a decrease in the use of radiation, the incidence of trilateral retinoblastoma has decreased dramatically, to the point that patients with the genetic form of retinoblastoma are now considered to be almost protected against this fatal complication.[132] However pineal cysts develop in approximately 5% to 8% of patients with bilateral disease; these cysts appear to be a forme fustre of trilateral retinoblastoma.[133,134,135]

The prognosis for patients with trilateral retinoblastoma is dismal—patients die of disseminated neuroaxis disease in fewer than 9 months.[125,127,131] The rare survivors are usually those diagnosed with screening imaging and treated with intensive chemotherapy with or without craniospinal radiation.[131] Because of the poor prognosis of trilateral retinoblastoma, screening neuroimaging is a common practice. One fourth of the cases in the literature correspond to cases found during screening.[131] Given the short interval between the diagnosis of retinoblastoma and the occurrence of trilateral retinoblastoma, routine screening might detect the majority of cases within 2 years.[131] Although it is not clear whether early diagnosis can have an impact on survival,[322] it is usually recommended that neuroimaging be performed every 6 months until 5 years of age.[127,131,323,324]

OTHER LONG-TERM EFFECTS

Orbital Growth and Facial Asymmetry

Because their orbital growth is still in progress, children treated for retinoblastoma are at risk of functionally and cosmetically significant bony orbital abnormalities. These sequelae become evident by early adolescence, when orbital growth is largely complete, and results in the “hourglass facial deformity.”[274] Both enucleation, which causes orbital contraction, and radiotherapy, which induces arrest of bone growth, adversely affect orbital growth. In children treated for bilateral retinoblastoma, the impact of enucleation in orbital development is not different from that of irradiation. Final orbital volumes after enucleation correlate with the size of the prosthetic implant, but there are no differences in final orbital volumes based on the type of implant.[275,365]

Delay of radiation therapy should therefore be a goal when designing treatment for children with bilateral retinoblastoma. Studies show that the therapeutic strategy of chemoreduction and aggressive focal treatments can successfully delay the use of radiation therapy for at least 6 or 7 months (median age, 21 months).[134,281] In addition to theoretically decreasing the risk of second cancers, delaying radiation therapy may also allow more complete facial and orbital growth to occur, thus reducing the degree of midfacial deformities.[274,275] However with the use of a multidisciplinary approach, the dose of radiation needed for disease control may also be reduced.[82]

Visual Outcome

Visual outcome is frequently good in children treated for retinoblastoma[366]; however maculopathy and deficits in acuity, visual fields, dark adaptation, and visuomotor integration have been reported for many patients.[269,366] Visual outcome correlates with the intraocular stage and, more importantly, tumor location. Visual acuity of 20/40 or better can be achieved in 90% of eyes with extramacular tumors and in 24% of eyes with macular tumors. Overall a final visual acuity of 20/40 or better may be achieved in half of the eyes, and two thirds have a visual acuity of 20/200 or better.[367] However visual outcome is not always easily predicted on the basis of the initial presentation.[368] These findings suggest that visual function in survivors of retinoblastoma is influenced by more distal elements of the visual system, including the primary visual cortex. Because retinoblastoma affects the visual system at an age at which the CNS is still developing,[369] differences in visual outcome among patients with retinoblastoma may be due, at least in part, to disease- or treatment-induced differences in visual field development in the primary visual cortex. New imaging technology such as functional MRI and diffusion tensor imaging may be used to evaluate changes in the visual pathways and the primary visual cortex.[370,371]

Cognitive and Functional Development of Patients with Retinoblastoma

Patients with retinoblastoma may experience a restriction in their development because of their visual limitations. However few studies have addressed the development of these young children. Interestingly the earliest articles describing cognitive development in this population suggested that children with retinoblastoma might have above average or superior intelligence.[372-375] These findings were based on a small number of patients and were never confirmed or unconfirmed, but the idea of superior intelligence became part of the “lore” among clinicians working with the retinoblastoma population. In the report of Ek and colleagues,[366] a population-based study from Sweden, 22 children with retinoblastoma were assessed at 4 and 6 years of age. Patients with both bilateral and unilateral disease showed above-average developmental quotients, with the bilateral group showing higher scores in the superior range. Only two children in the cohort demonstrated below-average development, and both of these patients had bilateral disease and received radiation therapy in the first month of life. The authors concluded that bilateral retinoblastoma is associated with superior cognitive capacities. The other recent series involved 54 patients who were assessed prior to the age of 42 months with the Bayley Scales of Infant Development.[269] No indication of superior intelligence was found in this cohort, but neither was there an indication of increased difficulties. The average mental and motor development scores were in the normal range and did not differ from population norms. Thus although children with retinoblastoma do not appear to be at-risk developmentally, questions regarding the developmental trajectory for this population remain.

Other Late Effects

Platinum compounds are commonly used to treat retinoblastoma. Although the effects of cisplatin on hearing are well documented, evidence is conflicting with regard to the potential ototoxic effects of carboplatin. Although it is usually assumed that carboplatin ototoxicity is extremely rare, very few studies have investigated the cumulative incidence of and prognostic factor for ototoxicity as a result of the use of this platinum agent. In two of the studies reported, no cases of carboplatin-induced hearing loss were documented.[376,377] However infants younger than 6 months appear to be at a higher risk of hearing loss.[378] Thus very careful age-appropriate evaluations of hearing function, including tympanometry, otoacoustic emission measurement, and visual reinforced audiometry, must be performed.[376,379]

CHAPTER OUTLINE

EPIDEMIOLOGY
NEURODEVELOPMENT
Neural Tube
Development of Brain Structures
Cancer Stem Cells
Genetic and Signaling Pathways Implicated in Development and in Pediatric Tumors
CONCEPTUAL ORGANIZATION OF PEDIATRIC BRAIN TUMORS
Obstructive Hydrocephalus and Raised Intracranial Pressure
IMAGING STUDIES
Neuroimaging
Surveillance Imaging
NEUROPATHOLOGY
TREATMENT STRATEGIES
Neurosurgery
Radiotherapy
Chemotherapy
Immunotherapy
Gene Therapy
Antiangiogenic Agents
Suppression of Tumor Resistance
High-Dose Chemotherapy with Stem Cell Rescue
PEDIATRIC BRAIN TUMORS
Gliomas
Oligoastrocytomas
Embryonal Tumors
Medulloblastomas
Pineocytomas and Pineoblastomas
Supratentorial or Central Nervous System Primitive Neuroectodermal Tumors
Atypical Teratoid Rhabdoid Tumors
Neurocytomas
Choroid Plexus Tumors
Germ Cell Tumors
Craniopharyngiomas
Infant Tumors
Other Tumors
LATE EFFECTS OF TREATMENT
Late Effects of Surgery
Late Effects of Radiation
Late Effects of Chemotherapy
PALLIATIVE CARE

Tumors of the central nervous system (CNS) account for approximately 25% of pediatric cancer but are now the leading cause of cancer-related mortality in children. The complexities of tumors in this site are related to the large number of different histologies within the CNS and a historic nomenclature that is confusing, even to those in this field. With the need to modify therapies to spare important neurocognitive function in the youngest patients and the presence of the blood-brain barrier (BBB), which restricts the delivery of effective therapies, improvement in outcome has lagged well behind that of many other cancers, especially childhood leukemia. The molecular revolution offers the chance to begin classifying tumors by the signals that drive their phenotype rather than by their appearance under the microscope.[1] In this chapter we will discuss the different types of brain tumors in children, their diagnoses, and their treatments, while incorporating the expanding knowledge of tumor biology.

Although clinical studies often focus on progression-free survival (PFS) and overall survival (OS), successful therapy incorporates much more. Accepting a lower overall cure rate but preserving neurocognitive function is the norm for many types of brain tumors, especially those of infants and young children. Optimization of outcome requires expertise in multiple subspecialties that play a role in the care of these children. The skill of the neurosurgeon, the sophistication of the radiation planning, and the safe administration of chemotherapy are all important factors in improving the long-term outcome

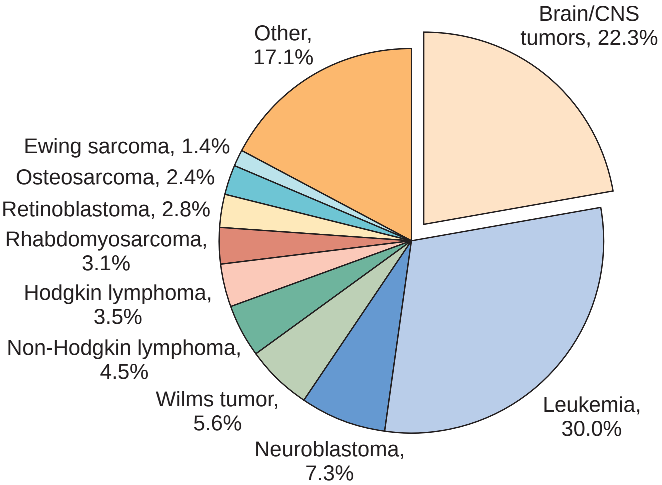

Figure 57-1 Incidence of pediatric cancer. *CNS*, Central nervous system. *(Data from American Cancer Society:* American Cancer Society Cancer Facts & Figures, 2007*, Atlanta, Ga, 2007, American Cancer Society.)*

for these patients.[2] In fact, many centers now use neurooncologists who have completed additional training in outcome optimization. When combined with a large number of subspecialty services (e.g., endocrinology, neurology, neuropsychology, social work, back to school, and physical and occupational therapy), truly optimal care is now possible for this patient population. Needs of the family continue to evolve as patients transition from diagnosis to treatment to posttherapy follow-up.[3,4] A comprehensive understanding of pediatric neurooncology and the delivery of comprehensive care to these patients and their families will be the focus of this chapter.

To assist the reader, a number of important review articles summarizing different aspects of the care of children with CNS tumors are referenced.[5-18]

EPIDEMIOLOGY

Primary CNS (PCNS) tumors rank second behind leukemia as the most common pediatric cancer diagnosed in the United States each year (Fig. 57-1). Brain tumors are the most common form of solid tumors in children and are now the leading cause of death from solid tumors in children. The spectrum of adult brain tumors[19] based on location, histology, and outcome differs significantly from that in pediatrics, suggesting that the causative events are different from those for pediatric brain tumors. No single standard classification system has been implemented for pediatric brain tumors, although development of a standardized platform for epidemiologic studies has been attempted.[20,21] The 2013 Central Brain Tumor Registry of the United States Statistical Report included primary nonmalignant (1.93 per 100,000 children) and malignant (3.33 per 100,000 children) pediatric brain and CNS tumors with a total incidence of 5.26 per 100,000 children.[22] Similarly in the 2013 National Cancer Institute Surveillance Epidemiology and End Results (SEER) Cancer Statistics Report, the annual age-adjusted incidence rate of pediatric malignant brain and other nervous system tumors was listed as 3.1 cases per 100,000 children.[23] The rate is higher in males (3.2 per 100,000) compared with females (2.9 per 100,000). Approximately 4100 new cases of childhood PCNS tumors are diagnosed in the United States each year. Of these, an estimated 3007 will be in children younger than 15 years. The incidence for all brain tumors is highest among 0- to 4-year-olds (5.77 per 100,000) and lowest among 10- to 14-year-olds (4.78 per 100,000), results that are similar to those reported in 2005.[21] The age-adjusted mortality rate for pediatric CNS tumors in 2010 was 0.6 per 100,000 children, resulting in an estimated 500 deaths per year in the United States for those aged 0 to 19 years. The prevalence rate for all malignant and benign pediatric CNS tumors (ages 0 to 19 years) is estimated at 9.5 per 100,000, with more than 26,000 children estimated to be living with this diagnosis in the United States in 2000. However the prevalence rate for patients with only malignant brain tumors was 7.9 per 100,000, with more than 21,000 children estimated to be living with a diagnosis of primary malignant CNS tumor in the United States in 2000.[24] The distribution of pediatric brain tumors by site is presented in Figure 57-2. Different brain tumor histologies have different age distributions (Fig. 57-3). The most common histologies in the younger age group (ages 0 to 14 years) include pilocytic astrocytomas (PAs) and medulloblastomas, which account for 20% and 16% of cases, respectively. The broad category of glioma accounts for 56% of tumors in children younger than 15 years. The most common histologies in adolescents ages 15 to 19 years include PA and pituitary tumors, which account for 15% and 14% of cases, respectively. The broad category of glioma accounts for 45% of tumors in adolescents ages 15 to 19 years. The rates among boys are slightly higher than those in girls, and brain tumors are more common in whites (4.7 per 100,000) than in blacks (3 per 100,000).

The histologic-specific differences in brain and CNS tumor distribution by age and gender suggest that childhood tumors have different mechanisms whereby normal cells, possibly somatic CNS stem cells, are susceptible to oncogenic mutation. Although certain histologic subtypes can also differ by race,[25,26] the overall concordance of tumor histologies among different ethnic groups and different locations suggest that specific local environmental factors are not the cause of most cancers in children.[27-29] The incidence of common pediatric brain tumors such as medulloblastoma, malignant gliomas, and diffuse pontine glioma do not differ significantly in industrialized versus nonindustrialized countries, in vegetarian versus meat-eating societies, and in areas where smoking and drinking are permitted versus where they are not permitted. Similarly death rates for children with CNS tumors between different ethnic groups within the United States (Hispanics, Asians, blacks, and whites) do not differ significantly for most CNS tumor types.[30]

In the mid 1990s an increase in the incidence of childhood brain cancer appeared to occur compared with that in the previous two decades. This increase is now thought to reflect the introduction and widespread use of

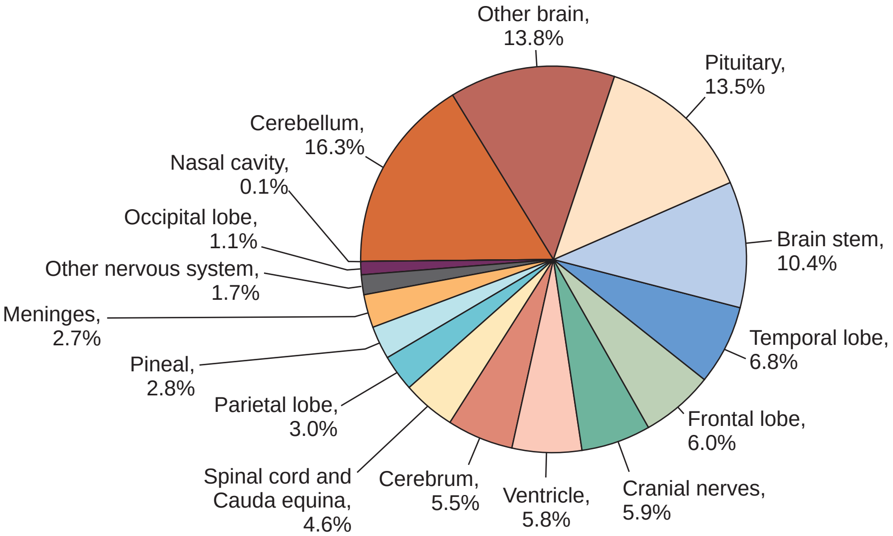

Figure 57-2 Distribution of childhood (ages 0 to 19 years) primary brain and central nervous system tumors by site ($n = 21{,}512$). *(Data from Ostrom QT, Gittleman H, Farah P, et al: CBTRUS Statistical Report: Primary Brain and Central Nervous System Tumors Diagnosed in the United States in 2006-2010.* Neuro Oncol *15[Suppl 2]:ii1–ii56, 2013; and Central Brain Tumor Registry of the United States:* 2007-2008 Statistical Report: Primary Brain Tumors in the United States Statistical Report, 2000-2004 [Years of Data Collected], *Chicago, Ill., 2008, University of Illinois at Chicago School of Public Health.)*

magnetic resonance imaging (MRI) technology in the mid 1980s, resulting in improved detection and reporting of pediatric brain tumors. More precise classification of brain tumors and diagnostic capabilities, such as stereotactic biopsy, also may have contributed to the increase in incidence. The rise in incidence was followed by the establishment of a new baseline that has remained stable. Mortality rates have not mirrored the increase in incidence.[31]

PCNS tumors develop from an accumulation of genetic changes. Such changes can result from inherited mutations or develop from exposure to chemical, physical, or biologic agents that damage deoxyribonucleic acid (DNA). Unlike in adults, for whom lifetime exposure is significant, most pediatric tumors are believed to be the result of random genetic mutations that occur during normal cellular proliferation. Today molecular biologic techniques are used to unravel the complex genetic errors that lead to the development of CNS tumors. To date most pediatric brain tumors have demonstrated a limited number of mutations, even in highly aggressive tumors, suggesting that their presence during development or within the stem cell compartment is an important aspect of tumorigenesis in pediatric patients.[32]

The search for causative factors that place children at risk for developing CNS tumors has not yielded clear answers.[33] Numerous epidemiologic studies have evaluated potential risk factors. Similar to most pediatric cancers, no specific risk factor explains more than a small proportion of tumors.[34] Factors studied but not conclusively found to increase risk include exposure to tobacco and smoke,[35] alcohol, traffic-related air pollution, electromagnetic fields, pesticides, and occupational and industrial chemicals; diet; drugs and medications; infections and viruses; epilepsy; and consumption of cured meats during pregnancy.[36-45] The dramatic increase in the use of cellular telephones has generated concerns about the potential risk for the development of brain tumors. A meta-analysis of nine case-control studies concluded that cellular phone users have no overall increased risk of brain tumors. The potential risk after long-term cellular phone use awaits analysis in future studies.[46] A seasonal variation unique to medulloblastoma incidence by month of birth may provide evidence for an environmental exposure cause, although further studies are needed.[47] An association between atopic disease and a reduced risk of glioma has been observed in adult epidemiologic studies, with the implication that heightened immune surveillance decreases the risk of brain tumor development.[33,48] Prenatal multivitamin use has been associated with a protective effect in the development of pediatric brain tumors in a large meta-analysis.[49] Confirmation of this result in a prospective trial is needed.

The role of viruses in the pathogenesis of tumors has been documented in experimental animals, and adenovirus serotypes have been shown to induce tumors in rodents. Adenoviral sequences were evaluated in more than 500 tumors derived from 17 different pediatric cancer entities. Although most leukemias and solid tumors were negative for the presence of adenoviral sequences, tumor material from 25 of 30 glioblastomas, 22 of 30 oligodendrogliomas, and 20 of 30 ependymomas, as well as normal brain, were positive by polymerase chain reaction assay for adenoviral gene sequences. This finding raises important questions about the contribution of this infectious agent to pediatric brain tumorigenesis.[50] In contrast, tests for polyomavirus sequences in adult and pediatric CNS tumors were rarely positive.[51]

Ionizing radiation, immunosuppression, and certain hereditary genetic disorders are the only factors that have been proven thus far to increase a child's risk for CNS malignancy. Ionizing radiation exposure is a

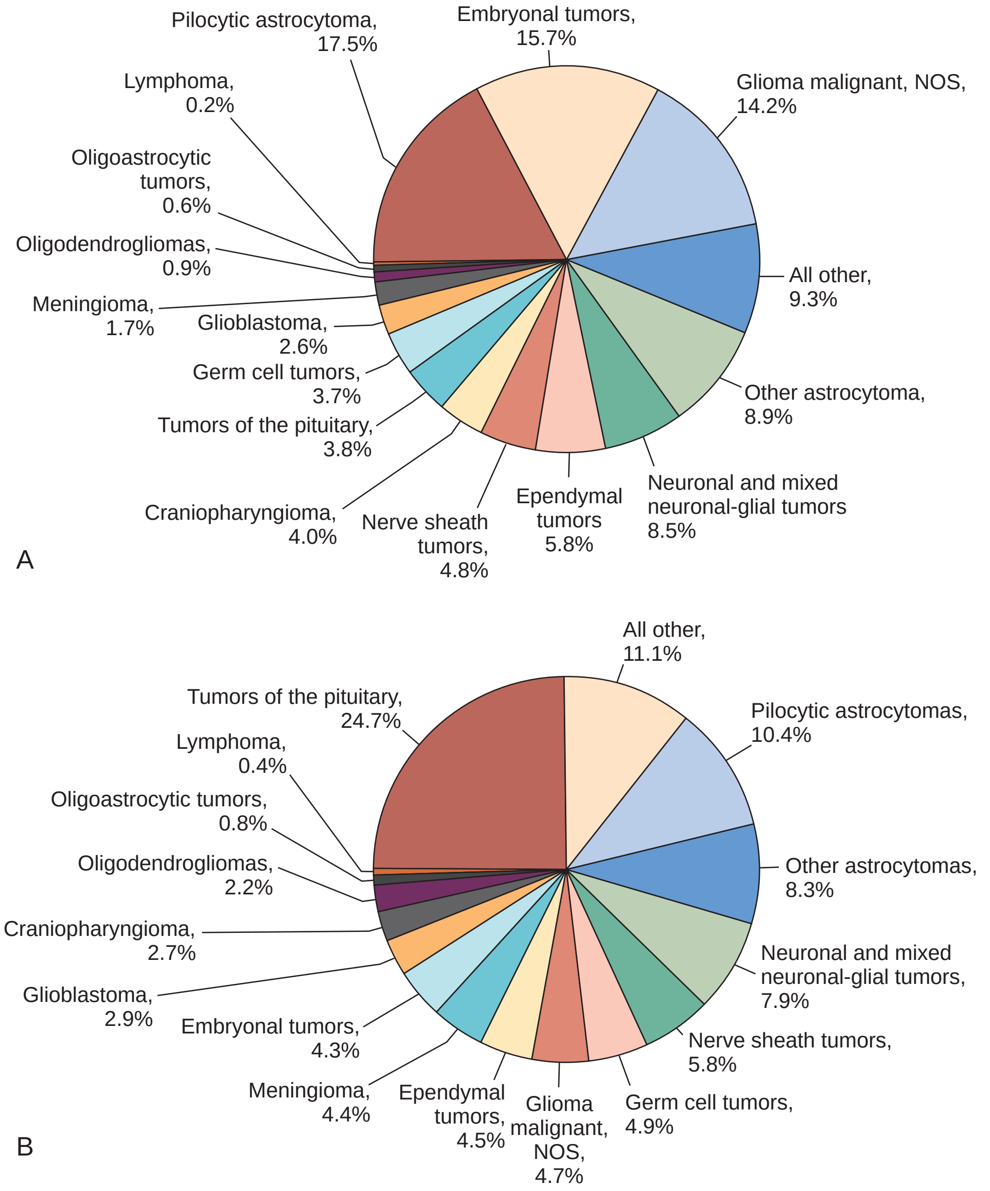

Figure 57-3 **A,** Distribution of childhood primary brain and central nervous system (CNS) tumors by histology and age (ages 0 to 14 years; $n = 15{,}398$). **B,** Distribution of childhood primary brain and CNS tumors by histology and age (ages 15 to 19 years; $n = 6114$). *NOS,* Not otherwise specified. *(Data from Ostrom QT, Gittleman H, Farah P, et al: CBTRUS Statistical Report: Primary Brain and Central Nervous System Tumors Diagnosed in the United States in 2006-2010.* Neuro Oncol *15:ii1–ii56, 2013.)*

well-documented cause of brain tumors.[52] Children who undergo therapeutic irradiation to the CNS for the treatment of malignancy are at risk for development of a second tumor, specifically meningioma, high-grade glioma (HGG), or sarcoma. Since its introduction in the 1970s, computed tomography (CT) has become an essential tool in the diagnosis and monitoring of disease. The growing use of CT scans has raised concerns about potential risks. Pediatric CT scans may result in a small but not negligible increased lifetime risk for cancer mortality.[53]

Immunocompromised children are at increased risk for PCNS lymphoma. The risk for developing CNS lymphoma is 1% to 5% higher for adults and children undergoing transplantation and for those with congenital immunodeficiencies. The risk is 2% to 6% higher for persons with acquired immunodeficiency syndrome (AIDS). This risk will probably increase with longer survival because of improved AIDS treatment.

In summary although a few environmental factors are associated with an increased risk of developing a pediatric CNS tumor, the vast majority of patients have no easily identifiable risk factors. For a small percentage, inherited genetic mutations contribute to the onset of these tumors, but for the remainder, CNS tumors are likely the result of spontaneous mutations.

NEURODEVELOPMENT

Our understanding of the steps in hematopoietic development, together with the pathways and markers that distinguish precursors along each blood cell lineage, has been instrumental in allowing better classification and subsequently better treatment of leukemias. In the same way that leukemias can be viewed as deregulated expansion of hematopoietic precursor cell pools, pediatric brain tumors may similarly be considered as the proliferation of neuropoietic precursors. Thus knowledge of the steps and intermediates in neural development may help us understand and treat pediatric brain tumors. A current schema for neuropoiesis relies heavily on models for hematopoiesis but introduces two additional aspects of developmental regulation, the first of which is the importance of regionalization. During neural development a rostral-caudal gradient delineates distinct zones for proliferation and differentiation, while the orientation of proliferating cells relative to the dorsal-ventral axis provides the basis for determining the progeny of each proliferative event.

The second aspect of neuropoiesis is the concept of mitogenic niches. Although hematopoietic stem cells can proliferate and give rise to the entire array of blood cell types when exposed to the environment of the immature or mature bone marrow, neural stem cells use a number of distinct niches, some of which are eliminated before birth, some that persist through early childhood, and some that remain extant into adult life. These niches provide important cues for proliferation and differentiation but may also provide an environment that fosters the growth of tumor cells.

Neural Tube

The nervous system develops as a specialized zone of the epithelium. In the third week after fertilization, the midline zone of the epithelium becomes specialized as the neural plate. This distinctive zone extends from the caudal to the rostral portion of the embryo. While the embryo turns, the neural plate grows and folds (Fig. 57-4). Subsequent fusion of the folds creates a discrete neural tube that zips up from both the top and bottom. The two last places where the fold fuses are the hindbrain (the incipient cerebellum) and the lumbar spine. Cells at the crest of the developing neural tube are the neural crest cells, which give rise to the peripheral nervous system, including sympathetic ganglia, dorsal root ganglia, and Schwann cells, as well as to melanocytes in the developing skin. The neural crest cells are the precursors to neuroblastomas,[54] neurofibromas,[55] and melanomas.[56]

After the neural tube fuses, rapid expansion of cell number continues, but this expansion occurs very differently along the rostral-caudal axis. The dramatic expansion of cell number in the rostral neural tube provides the building blocks for the brain, whereas the more caudal regions undergo more limited growth and engender the spinal cord.

Development of Brain Structures

Along the rostral-caudal axis of the neural tube, three outpouchings can be seen at the end of the fourth week after fertilization—the forebrain, midbrain, and hindbrain (Fig. 57-5). Subsequent branching of the forebrain forms two lateral protrusions that are destined to become the left and right cortex, and the midline portion of the forebrain gives rise to the thalamus. The midbrain does not undergo much expansion, but the hindbrain undergoes massive proliferation to give rise to the cerebellum and underlying pons, as well as the medulla. Cerebral cortical tumors, including supratentorial primitive neuroectodermal tumors (CNS PNETs) and cortical and subependymal astrocytomas, all derive from the forebrain. Posterior fossa tumors, including the distinctive pontine gliomas, medulloblastomas, and cerebellar PAs, all derive from the hindbrain. Thus the areas of the brain that undergo rapid expansion in early life engender most pediatric brain tumors. Along the dorsal-ventral plane of the neural tube, greater proliferation of neural tube precursors occurs in the dorsal part of the tube than in the ventral tube. Proliferation of more dorsal precursors gives rise to the multilayer structures of the cerebral and cerebellar cortex; these areas are also the regions that give rise to many pediatric brain tumors.

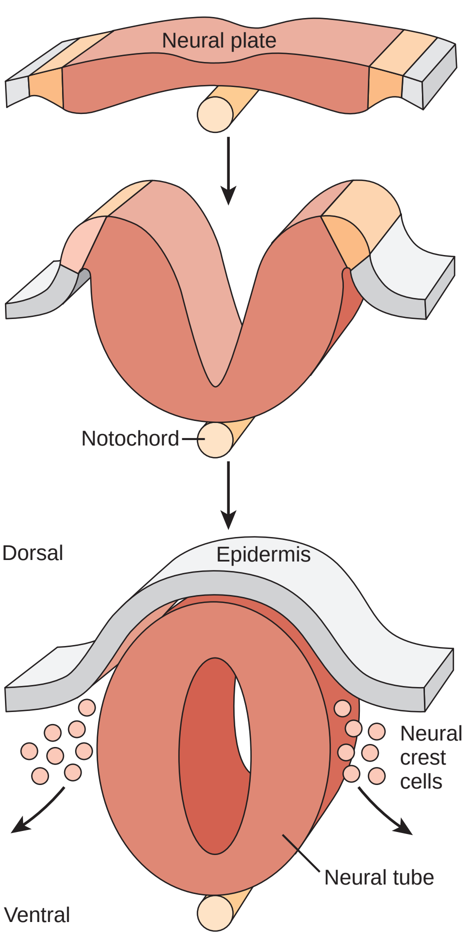

Figure 57-4 Growth and folding of the neural plate.

Forebrain and Cerebral Cortex

In the forebrain the open spaces within the lateral outpouchings of the neural tube become the lateral ventricles, and proliferation largely occurs adjacent to the ventricular zone (VZ) in the medial and lateral ganglionic eminences, in the subventricular zone (SVZ) or subependymal zone. Early in development, neural stem cells/precursors divide extensively to provide the cellular elements of the cerebral cortex, thalamus, and basal ganglia (see Fig. 57-5, *A*).

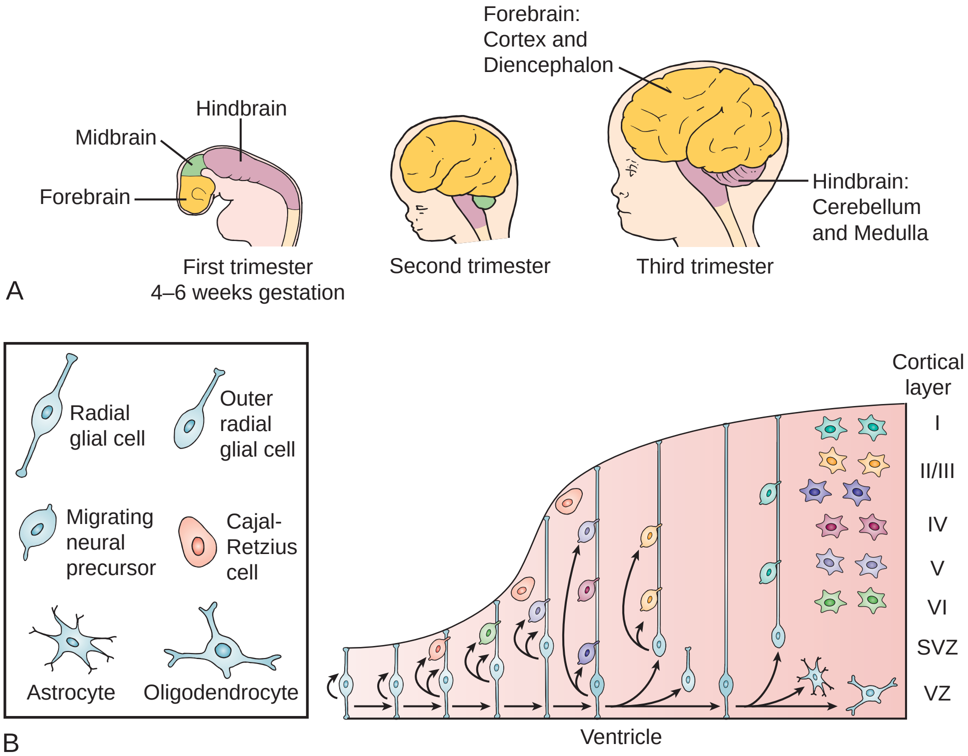

Figure 57-5 **A**, Outpouching of the neural tube. **B**, Cortical Development process. Radial Glia (RG) function as neural stem/precursor cells. Initially, the population of RG expands by proliferation, and the early RG produce a largely transient population of Cajal-Retzius cells. RG continue to proliferate and produce: (1) outer RG located in the Subventricular zone *(SVZ)*, (2) more RG, and (3) early cortical neurons. Neurons produced by the RG and the outer RG migrate along the RG to the cortex. Neurons are generated in an inside-out pattern so that the earliest neurons are found in the deep cortical layers. After most of the neurons have been generated, RG give rise to astrocytes and oligodendrocytes. The cell of origin for astrocytomas may be residual RG, outer RG, or astrocytes.

Although the VZ in the forebrain initially contains the dividing neural stem/progenitor cells, during development the size of the VZ progressively decreases while the adjacent SVZ increases in size. The early generated cells migrate radially from the VZ and SVZ to become the neurons of the innermost cortical layer (layer VI), and later mitoses give rise to neurons that also migrate radially and occupy increasingly superficial layers. Inhibitory neurons are derived from precursors in the medial ganglionic eminence. They migrate tangentially throughout the cortex. Thus the cortex develops in an inside-out pattern. Toward the end of the prenatal neurogenic phase, the precursors of the VZ and SVZ generate glial cells, including astrocytes, oligodendrocytes, and ependymal cells.[57,58]

A small population of precursors remains in the SVZ, just above the ependymal cells, throughout life. These neural stem cells continue to generate glial cells and oligodendrocytes and also continue to give rise to a limited number of neuronal cells through adult neurogenesis. An additional zone of adult neurogenesis is located in the hippocampus, adjacent to the granular zone. Thus the neural stem cell represents a common precursor for glial and neuronal cells. Accumulating data suggest that many, if not most, brain tumors arise from such stem cells or their early derivatives.

Cerebellar Cortex

The cerebellar cortex develops in a way that has some similarities to, but some differences from, the pattern in the cerebral cortex. The hindbrain is the site where the neural tube closes last. While closure occurs, the neural folds pucker to form the rhombic lips. These two protrusions will give rise to many cell types of the cerebellum and pons. Cells in the VZ of the upper rhombic lip proliferate and then begin an unusual migration pattern. The precursor cells of the rhombic lip migrate over the top of the rhombic lip and disperse by moving from the caudal aspect of the pucker to cover the rhombic lip or incipient cerebellum. The rhombic lip–derived precursors settle in a zone that covers the developing cerebellum, which is called the external granule cell (external germinal cell [EGL]) layer. This layer constitutes a site of extensive postnatal proliferation and is a specialized mitogenic niche where precursors divide and give rise almost exclusively to cerebellar granule cells, the most numerous neuronal cells in the brain. This secondary proliferative zone may be necessary to generate this vast number of granule cells. To generate the 60 to 80 billion granule cell neurons, the granule cell precursors in the EGL undergo many rounds of cell divisions, beginning in the ninth week after fertilization and continuing through the first 18 months of life in humans. Other stem/precursors in the VZ follow distinct differentiation paths. Radial glia adjacent to the cerebellum provide one source of these multipotential stem/precursors. Some VZ stem/precursors migrate toward the cerebellar white matter, where they can give rise to cerebellar interneurons and glia. Others migrate past the cerebellar white matter and form the Bergmann glia of the cerebellar cortex.

It has been suggested that four distinct subtypes of cerebellar stem/precursors each give rise to a distinct subtype of medulloblastoma. A great deal of evidence has indicated that the granule cell precursors of the EGL are a cell of origin for the sonic hedgehog (SHH) subtype of medulloblastoma.[59] First, in very young children, medulloblastomas are often continuous with the EGL, and an intermediate zone of dysplastic cells can sometimes be seen to join the EGL and tumor tissue. Second, the appearance and pattern of gene expression of the granule cell precursors resemble those of SHH-type medulloblastoma. Finally, SHH signaling pathways that normally regulate proliferation of granule cell precursors are constitutively active in one type of medulloblastoma (discussed later).

The precursor cells adjacent to the ventricle that resemble radial glia have been suggested to be the cells of origin of Wingless (Wnt)-subtype medulloblastomas. In mouse models, activation of the Wnt pathway and/or activation of phosphoinositide 3′ kinase (PI3K) in these radial glial precursors can mimic this group of medulloblastomas.

The cellular origin and the oncogenic mutations responsible for initiating other medulloblastoma subtypes have also been identified. For example, it has been suggested that the stem cells of the white matter and earlier stem cells may provide the cellular origin for group III and IV medulloblastomas, respectively.[60] It has been suggested that less specialized stem cells can give rise to medulloblastomas. Indeed molecular characterization of medulloblastomas suggests that genetically distinct tumor types exist that may represent the oncogenic transformation of cerebellar precursor cells at different locations and stages.[61,62] This scenario would be analogous to leukemias, in which oncogenic transformation of hematopoietic precursors at distinct developmental stages leads to distinct types of leukemias.

Cancer Stem Cells

Brain tumors have predominantly been classified as neuronal or glial in nature. The neuronal tumors include CNS PNETs, pineoblastomas, and medulloblastomas, as well as ganglion cell tumors. Glial tumors include many different gliomas, such as juvenile PA, subependymal giant cell astrocytoma, other low-grade astrocytomas, pontine glioma, malignant astrocytoma (including glioblastoma multiforme), and tumors that resemble other glial cell types, such as oligodendroglioma and ependymoma. Although this classification schema remains useful, it appears that many brain tumors are generated by oncogenic mutations in neural stem–precursor cells, rather than more mature cell types. Furthermore although cancers traditionally have been viewed as clonal, increasing evidence indicates that this is not the case. Instead the concept of the existence of a subpopulation of cancer stem cells has developed—distinctive cells within the tumor that are uniquely capable of regenerating the cancer.[63] Recent studies of brain tumors have identified cluster of differentiation (CD)-133–positive cells as radioresistant, slowly proliferating cancer stem cells that are particularly prevalent in high-grade tumors, such as glioblastoma multiforme. The ability of these cancer stem cells to survive surgical resection, radiation, and cytotoxic chemotherapy is a major reason for the difficulty in curing high-grade brain tumors.

Genetic and Signaling Pathways Implicated in Development and in Pediatric Tumors

Inherited disorders that cause a familial propensity for brain tumors have provided an important method for identifying genetic pathways that contribute to these cancers.[64-68] Neurofibromatosis, tuberous sclerosis, Gorlin syndrome, Turcot syndrome, Cowden syndrome, and the *SMARCB1* (switch/sucrose nonfermentable [SWI/SNF]–related, matrix-associated, actin-dependent regulator of chromatin, subfamily b, member 1) mutation all represent heritable disorders associated with an increased risk of brain tumors (Table 57-1).[69]

Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF-1) is an autosomal-dominant neuroectodermal disorder characterized by café-au-lait spots and fibromatous tumors of the skin. Additional clinical features that can be seen in NF-1 (Box 57-1) include Lisch nodules in the iris, scoliosis, cognitive problems, and epilepsy.[70-72] Several tumors occur with greater frequency in persons with this disorder, including pheochromocytoma, ependymoma, meningioma, and glioma; this characteristic may relate to dysregulation of specific stem cell populations.[73] Among these tumors, gliomas of the optic pathway are the most common tumors seen.[74] The unique biology of these tumors is slowly being elucidated through studies of the role of NF-1 in the development of the optic pathway in animal models.[75] Neurofibromatosis is caused by heterozygous mutations in neurofibromin, and the cancers observed in this disorder result from loss of heterozygosity at chromosome 17q11.2, leaving only the mutant NF-1 allele.[76] Although this disorder is inherited as an autosomal-dominant disease, as many as 50% of patients represent new germline mutations and therefore do not have a family history of the disorder.

The neurofibromin protein is a 250-kD tumor suppressor that functions as a guanosine triphosphatase activator for the small G protein Ras.[77] In this way, active neurofibromin decreases the ratio of guanosine triphosphate–bound (active) to guanosine diphosphate–bound (inactive)

TABLE 57-1 Common Chromosomal Abnormalities Associated with Pediatric Central Nervous System Tumors

Chromosomal Abnormality	Tumor
Monosomy 22	Atypical teratoid-rhabdoid tumor Acoustic neuromas Meningioma Ependymoma
1p and/or 22q loss	Oligodendroglioma
Isochrome i17	Medulloblastoma
9q22 loss (*PTCH1* gene)	Medulloblastoma
Loss of chromosome 10, 9p, 17p	Progression to high-grade glioma

Ras or Ras-like protein. While activated Ras stimulates mitogen-activated protein kinases (MAPKs) and PI3Ks, the change in Ras activity leads to unregulated proliferation and survival (Fig. 57-6).[78] Although the incidence of brain tumors, particularly optic nerve gliomas, is significantly increased in persons with NF-1 (approximately 5% to 15%), the tumors that develop in these patients tend to be less aggressive than other gliomas. These tumors are more susceptible to chemotherapeutic interventions and thus can be treated differently than other gliomas. In fact many tumors stop growing spontaneously. The unique developmental environment of the optic pathways may account for the differential occurrence of these tumors in patients with NF-1, as well as their increased responsiveness.[79] In addition to optic pathway gliomas (OPGs), non-OPGs occur at frequencies 100 times greater than expected, with the most common sites being the brainstem (49%), cerebral hemispheres (21%), and basal ganglia (14%). Other MRI signal abnormalities within the brain are often observed in patients with NF-1.[80,81] The most characteristic abnormality is the unidentified bright object.[82] Unlike low-grade gliomas (LGGs), these lesions are bright on T2-weighted imaging, do not demonstrate contrast enhancement, and usually produce neither mass effect nor symptoms. They often come and go and should not be biopsied or treated. The varied intracranial localization of lesions and variable need for neurosurgical intervention in a subset of children with NF-1 suggests that radiologic surveillance should be based on careful and regular neurologic and ophthalmologic examinations.[83]

Box 57-1 Diagnostic Criteria of Neurofibromatosis Type 1*

Six or more café-au-lait spots ≥1.5 cm in postpubescent individuals or >0.5 cm in prepubescent individuals
Two or more neurofibromas or one or more plexiform neurofibromas
Freckling in the axillae or groin
Optic glioma
Two or more Lisch nodules
Dysplasia of the sphenoid bone or dysplasia or thinning of the cortex of long bones
A first-degree relative with neurofibromatosis type 1

*The diagnosis of neurofibromatosis type 1 requires any two or more of these criteria.

Patients with NF-1 appear to be at increased risk of moyamoya syndrome,[84,85] and this risk becomes especially high after cerebral radiation therapy. Patients with NF-1, even in the absence of a brain tumor, are also affected by a number of other problems as a result of their disease, in particular neurocognitive impairment, which can range from mild to severe.[78]

Neurofibromatosis Type 2 (Merlin)

Neurofibromatosis type 2 (NF-2) is characterized by familial, bilateral acoustic neuromas and is caused by mutations in the gene that encodes merlin, or schwannomin, localized to chromosome 22q12.2.[86,87] Merlin interacts with cytoskeletal components and appears to be important in adhesion-dependent growth control. Persons with germline mutations also have skin tumors with both peripheral schwannomas and neurofibromas and have a propensity to develop intracranial meningiomas or, more rarely, gliomas and spinal tumors.[88] The onset of symptomatic tumor growth is uncommon in childhood, and in most patients the condition is identified in adulthood.

Tuberous Sclerosis

A third neurocutaneous disorder associated with an increased propensity for brain tumors is tuberous sclerosis (TS). This condition can be caused by mutations in either of two genes, *TSC1* (hamartin, at chromosome 9q34)[89] or *TSC2* (tuberin, at chromosome 6p), and it is characterized by hamartomata in multiple organs. The most common clinical manifestations include epilepsy, cognitive and behavioral problems, and characteristic skin lesions. The white leaf-shaped skin lesions can best be seen under a Wood light; adenoma sebaceum (facial angiofibroma) can also be seen. Renal manifestations include angiomyolipomas, renal cysts, and, more rarely, renal cell cancer. Brain tumors develop in between 5% and 14% of patients, the most common being the subependymal giant cell astrocytoma (SEGA); other gliomas and ependymomas are also relatively frequent. Careful serial evaluations are required because of the possibility of additional tumor development in this patient population.[90] Cortical tubers can cause seizures and require specialized neurosurgical approaches in children.[91] Resection of tubers does not always control seizures and suggests that extratuberal epileptogenic brain abnormalities may be present that require more specialized imaging.[92]

The phenotypic similarity of mutations in Tsc1 and Tsc2 is explained by the finding that these two proteins interact directly with one another.[89] This complex acts as a guanosine triphosphatase–activating protein for Ras homolog enriched in brain (Rheb). The decreased activity of Rheb inhibits the mammalian target of rapamycin (mTOR) and p70 ribosomal S6 kinase–1. As a result there is diminished translation by eukaryotic translation initiation factor 4E-binding protein–1 (EIF4EBP1; 602223). The hamartin-tuberin complex thereby regulates growth and proliferation of subependymal and subventricular neural stem cells. The Tsc-mTOR pathways may normally be regulated by Wnt and insulin-like growth factor (IGF) ligands during development. Patients with TS who have SEGA or LGGs have demonstrated responses to mTOR inhibitors, confirming the clinical relevance of these findings.[93]

Gorlin Syndrome

Gorlin syndrome (also known as basal cell nevus syndrome or nevoid basal cell carcinoma syndrome) is characterized by multiple basal cell carcinomas or basal cell nevi before the age of 30 years, odontogenic keratocysts or polyostotic bone cysts, and palmar and plantar pits. Other manifestations include rib or vertebral anomalies, large head circumference with frontal bossing, cardiac or ovarian fibroma, and lymphomesenteric cysts.[94] Gorlin syndrome is caused by mutations in PTCH1 (chromosome 9q22.3), the receptor for the SHH ligand.[95-100] Medulloblastoma develops in approximately 4% to 10% of persons with Gorlin syndrome. This syndrome also predisposes to other tumors, such as rhabdomyosarcoma and meningioma.[101,102]

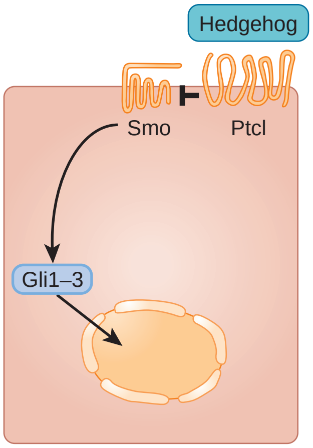

Figure 57-7 The PTCH1 gene product functions as both a receptor and negative regulator of signaling initiated by sonic hedgehog or the related ligands, Indian hedgehog and desert hedgehog. These ligands initiate an unusual and incompletely understood signaling pathway that culminates in Gli1-3 initiating transcription of cell cycle genes, including cyclin D1 and D2. *Smo,* Smoothen.

The PTCH1 gene product functions as both a receptor and negative regulator of signaling initiated by SHH or the related ligands, Indian hedgehog and desert hedgehog. These ligands initiate an unusual and incompletely understood signaling pathway (Fig. 57-7). When a hedgehog ligand binds to Ptc, this alters the activation state of smoothened, or Smo, a seven-transmembrane protein. Normally Ptc represses the activity of Smo; however, when a ligand binds to Ptc, this derepresses Smo activity. Active Smo translocates to a distinctive subcellular organelle known as a primary cilium. Here active Smo enables the dissociation of a signaling complex containing suppressor of fused homolog (SUFU) and Glioma-associated Oncogene Homolog (Gli) transcription factors. The dissociation of this complex results in the nuclear relocalization of Gli family members and increased expression of Gli family members, as well as the expression of v-myc avian myelocytomatosis viral oncogene neuroblastoma derived homolog (MYCN), D-type cyclins, and the stem cell–associated chromatic complex component, B lymphoma Mo-MLV insertion region 1 homolog (Bmi-1). The active pathway thereby potentiates proliferation and inhibits apoptosis.

Good evidence indicates that constitutive activity of the SHH pathway can cause medulloblastoma. Gorlin syndrome is associated with increased incidence of medulloblastoma, as is the analogous mutation in mice. Activating mutations in Smo, or mutations in suppression of fused (SuFu), can also lead to these brain tumors. Recent studies have suggested that specific inhibitors of Smo may provide valuable biologic therapies for medulloblastoma.

The value of understanding developmental pathways that normally regulate neural precursor proliferation to decipher the mechanisms that cause pediatric brain tumors is reinforced by data showing that SHH ligand stimulates and regulates proliferation of granule cell precursors and neural stem cells. Thus it is perhaps not surprising that SHH-responsive genes are also expressed in gliomas, including diffuse intrinsic pontine gliomas (DIPG) and glioblastoma. Thus inhibitors of SHH signaling may play a role in treating several types of brain tumors.[103]

Turcot Syndrome

Turcot syndrome is characterized by familial polyposis of the colon, together with malignant brain tumors. This disorder can be caused by mutations in the adenomatous polyposis coli gene (*APC*, on chromosome 5q21) or in the mismatch repair genes *MLH1* (120436) or *PMS2* (600259). The distinction between the clinical entities that result from mutations in *APC* and mutations in repair genes[104] include the nature of the brain tumors seen; the characteristic brain tumors seen are medulloblastomas or astrocytomas, respectively.[105] APC is a large protein whose activity is critical in the Wnt signaling pathway. Therefore inactivating mutations of *APC* result in the aberrant accumulation of β-catenin and increased transcription of transcription factor 4 (Tcf4)-dependent genes, including *c-myc*. Mutations in β-catenin and in APC have also been reported in sporadic medulloblastoma,[104] highlighting the importance of this pathway for this malignant cerebellar tumor.

Wnts constitute a family of ligands that can act through two distinct signaling pathways. The canonical Wnt pathway is initiated when Wnt proteins bind to cell-surface receptors of the Frizzled family. This binding leads to activation of Dishevelled (DSH) family proteins. When DSH becomes activated, it inhibits a protein complex that includes axin, glycogen synthase kinase–3 (GSK3), and APC (Fig. 57-8). The axin–GSK3–APC complex promotes the proteolytic degradation of β-catenin. After this β-catenin destruction complex is inhibited, cytoplasmic β-catenin becomes stabilized and β-catenin is then able to enter the nucleus. Nuclear β-catenin interacts with TCF-LEF (lymphoid enhancer-binding factor 1) family transcription factors to promote the expression of a gene program that includes c-myc, N-myc, and cyclin D1 and thereby stimulate cell cycle progression (Fig. 57-9). It is not clear whether the non-canonical Wnt pathway, which does not involve APC, also contributes to brain tumors.

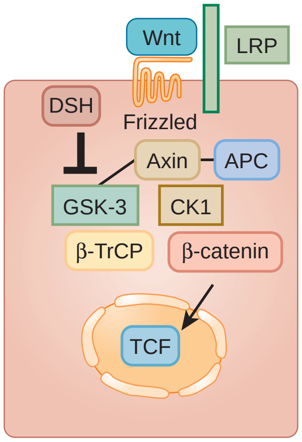

Figure 57-8 Wnts are a family of ligands that can act through two distinct signaling pathways. The canonical Wnt pathway is initiated when Wnt proteins bind to cell-surface receptors of the Frizzled family, which leads to activation of Dishevelled family proteins. When Dishevelled *(DSH)* is activated, it inhibits a protein complex that includes axin, glycogen synthase kinase 3 *(GSK-3)*, and adenomatous polyposis coli *(APC)*. The axin/GSK-3/APC complex usually promotes degradation of β-catenin. After this β-catenin destruction complex is inhibited, cytoplasmic β-catenin becomes stabilized so that it is able to enter the nucleus. Nuclear β-catenin interacts with the transcription factor *(TCF)* family transcription factors to promote expression of a gene program that includes cyclin-D and thereby stimulates cell cycle progression. *CK1*, Casein kinase 1; *LRP*, lipoprotein receptor-related protein; *β-TrCP*, beta-transducin repeat containing protein.

Oncogenic events can increase cyclin-D (i.e., hedgehog or Wnt signals) or alter other cell cycle regulators. *Cdc2,* Cell division cycle protein 2 homolog; *CDK,* cyclin-dependent kinase; *Rb dephos'n,* retinoblastoma 1 dephosphorylated; *Rb phos'n,* retinoblastoma 1 phosphorylated.

As is the case for SHH signaling, the ability of the deregulated Wnt pathway to cause medulloblastomas highlights the relevance of understanding neurodevelopment. In the absence of Wnt1, the cerebellum does not form properly.[106] The Wnt and SHH pathways cooperate during normal development to generate normal cerebellar neurons. It is likely that these pathways also synergize in tumor formation, particularly during medulloblastoma oncogenesis.

Lhermitte-Duclos Disease, Cowden Syndrome, and *PTEN* Mutation

Activation of PI3K results in phosphorylation of phospholipids at the 3′ position; this phosphorylation is removed by the phosphatase and tensin homolog *(PTEN)* phosphatase. Therefore mutations in *PTEN* result in excess and/or incorrectly localized activation of the PI3K pathway. PI3K is critical in several signaling pathways that regulate proliferation, survival, migration, and cell size. The multiplicity of functions explains the diverse spectrum of disorders seen in *PTEN* mutations, including neurologic, cutaneous, and oncologic syndromes.

Molecular studies on Lhermitte-Duclos disease (LDD) tissue have revealed *PTEN* gene mutations in 83% of cases, with immunostaining showing lost or reduced *PTEN* expression in 78% of cases. As a consequence, Akt phosphorylation is increased.[107] Initially Cowden syndrome was described as a familial predisposition for breast cancers, thyroid cancers, brain tumors, and other neoplasia. This syndrome was subsequently recognized as a spectrum of disorders that includes LDD and Bannayan-Ruvalcaba-Riley syndrome. The diagnosis of LDD depends on characteristic hamartomas of the cerebellum. These lesions in the cerebellar cortex exhibit thickened cerebellar folia, with misplaced cerebellar granule cells and enlarged size of the cerebellar neuronal cell bodies. In addition to cerebellar ataxia, these hamartomas can cause hydrocephalus and herniation. Another manifestation of the *PTEN* mutations is seen in Bannayan-Ruvalcaba-Riley syndrome, with macrocephaly, seizures, cognitive dysfunction, and autistic behaviors. Different manifestations of the mutation can be observed even within a family, and thus a careful consideration of family history is warranted.

RB1 Mutations

The retinoblastoma gene was the first tumor suppressor gene identified. In addition to the retinal tumors seen in persons with germline mutations in *Rb1*, “trilateral” retinoblastoma has been described. In these persons, bilateral retinoblastoma is accompanied by a pineal tumor (pineoblastoma) with similar characteristics to retinoblastoma. The other secondary tumors that occur in patients with retinoblastoma are osteosarcomas. The Rb1 protein is required for the G1 checkpoint, and studies on this pathway have provided key insights into the mechanisms of growth regulation.

Atypical Teratoid Rhabdoid Tumor

Mutations in the sucrose nonfermentable 5/integrase interactor 1 (SNF5/INI1) component of the SWI-SNF DNA remodeling complex cause rhabdoid tumors. These tumors include renal and soft tissue tumors and brain tumors. In the CNS, these brain tumors, called atypical teratoid rhabdoid tumors (ATRTs), are characteristically found in the cerebellopontine angle or in supratentorial locations. Prior to the identification of deletions or mutations of the *SMARCB1* gene on chromosome 22, these tumors were historically grouped with medulloblastomas and PNETs. However their histology is distinct, with a mixture of atypical spindle cells, poorly differentiated small round blue cells, and rhabdoid cells with prominent cytoplasmic inclusions, large eccentric vesicular nuclei, and adjacent whorls of intermediate filaments. The nature of the cell of origin for these tumors, and why they predominantly arise in very young children, is as yet poorly understood.

CONCEPTUAL ORGANIZATION OF PEDIATRIC BRAIN TUMORS

Leukemias are considered in the context of their lineage and stage of development, whereas neuroblastoma is evaluated by the extent of spread, age of the child, and molecular phenotype. Neither of these approaches is well suited to CNS tumors. Although brain tumors share an anatomic site, a number of unique cell types, significant heterogeneity in distribution, and differences in the consequence of therapy differ according to the age of the patient and location within the CNS. These factors, combined with a complicated historic nomenclature, require a different approach to understanding these tumors.

The CNS is made up of three major elements, and therefore three major groups of tumors are commonly observed:

1. Glial cells—responsible for structural support and maintenance of the CNS, and composed of three cell subtypes:
    a. Astrocytes—structural support for the CNS → astrocytoma
    b. Ependymocytes—help regulate homeostasis of the CNS → ependymoma
    c. Oligodendrocytes—myelination for the neural axons → oligodendroglioma
2. Neurons—electrical activity → medulloblastoma, pineoblastoma, CNS PNETs
3. Choroid plexus—production of cerebrospinal fluid (CSF) → choroid plexus carcinoma (CPC)

Tumors arising from glia, neurons, or the choroid plexus account for approximately 90% of all pediatric CNS tumors. The remaining 10% of pediatric brain tumors arise from cells that are derived from extracranial sources but become entrapped in the developing CNS during embryogenesis (Fig. 57-10).

4. Germ cells, which arise in the primordial gonadal ridge and normally migrate down to their final resting place in the abdomen (ovaries) or scrotum (testes), can occasionally migrate upward and become enveloped in the developing brain → germinoma, nongerminomatous germ cell tumor (NGGCT)
5. Cells from the Rathke pouch, which normally gives rise to structures of the head and neck, can become trapped within the developing brain → craniopharyngioma

Two additional tumor types that are rare in children but account for approximately 80% of CNS tumors in

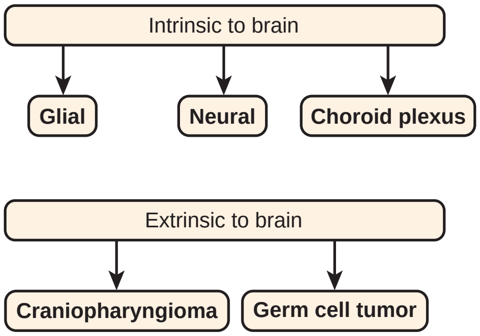

Figure 57-10 Most pediatric brain tumors can be classified into one of five different categories, based on cell of origin. Glial, neuronal, and choroid plexus tumors account for those that derive from cells within the central nervous system (CNS), while germ cell tumors and craniopharyngiomas arise from cells that are enclosed in the developing CNS in early development as a result of abnormal migration.

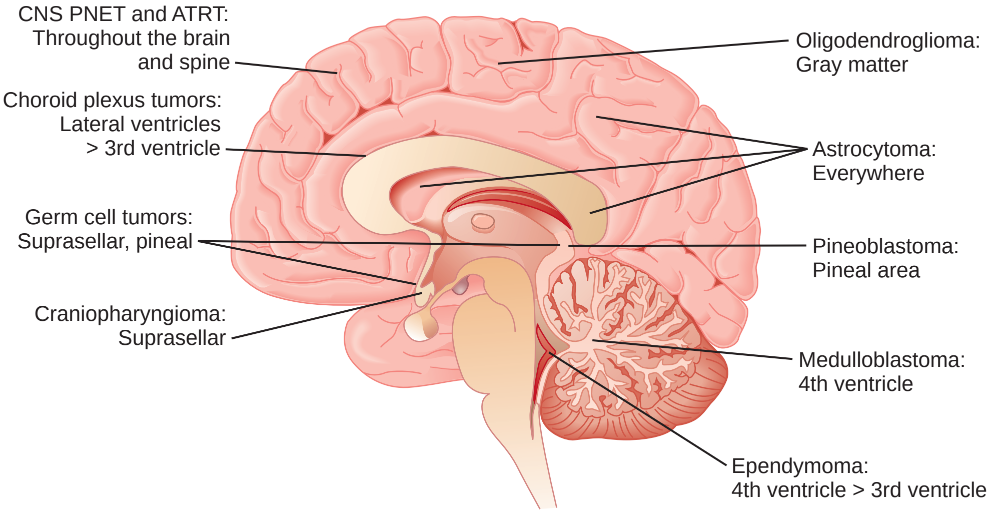

CNS PNET and ATRT: Throughout the brain and spine
Choroid plexus tumors: Lateral ventricles > 3rd ventricle
Germ cell tumors: Suprasellar, pineal
Craniopharyngioma: Suprasellar
Oligodendroglioma: Gray matter
Astrocytoma: Everywhere
Pineoblastoma: Pineal area
Medulloblastoma: 4th ventricle
Ependymoma: 4th ventricle > 3rd ventricle

Figure 57-11 Common distributions of different pediatric central nervous system *(CNS)* tumor histologies. *ATRT,* Atypical teratoid/rhabdoid tumor; *CNS PNET,* primitive neuroectodermal tumor.

adults include metastatic carcinoma, especially of the breast, colon, lung, and prostate. Metastatic lesions to the brain in pediatric patients are exceptionally rare, and when they occur, they are usually in the context of end-stage disease.[108-110] Meningiomas are the other common adult brain tumor that is rarely observed in children.

The five primary cell types of the brain are not evenly distributed in the CNS (Fig. 57-11):

1. Glia.
    a. Astrocytes are found throughout the entire brain and spine.
    b. Ependymocytes line each of the ventricles, and hence these cells are most predominant in the 4th ventricle > 3rd ventricle.
    c. Oligodendrocytes are found around the junction of the gray-white matter.
2. Neural tumors are defined by location rather than histology; molecular characterization indicates that these distinctions based on location are biologically important.
    a. Medulloblastoma is found within the posterior fossa.
    b. Pineoblastoma is found within the pineal region.
    c. CNS PNETs can be found anywhere in the brain or spine.
3. Choroid plexus is predominantly located in the lateral ventricles.
4. Germ cell tumors (GCTs) are localized to the suprasellar region, the pineal area, or both.
5. Craniopharyngiomas are found within the suprasellar region.

Brain tumors tend to spread in one of two ways, by direct invasion into adjacent regions with focal expansion of the primary mass, or by dissemination (seeding) of cells through the CSF, with resultant multifocal disease. Of the five tumor types listed, glial tumors and craniopharyngiomas tend to grow by direct extension and the other three tend to grow by seeding cells into the CSF. The workup of patients with newly diagnosed brain tumors will therefore require MRI of the involved area for glial tumors and craniopharyngioma, and craniospinal imaging and CSF cytology will be needed for seeding tumors (neural, choroid plexus, and germ cell).

Three major treatment strategies are considered for all CNS tumors: (1) surgery, (2) radiotherapy, and (3) chemotherapy. Certain general principles can be applied to their use (Table 57-2):

1. Surgery is important for making the diagnosis, achieving rapid reduction in tumor size, and relieving elevated pressure from obstructive hydrocephalus.
2. Radiotherapy is effective for a wide range of tumors but has significant morbidity on the developing CNS, which frequently limits its applicability. In general focal tumors (gliomas and craniopharyngiomas) are treated with focal radiation therapy, whereas seeding tumors (medulloblastomas, pineoblastomas, CNS PNETs, CPCs, and GCTs) are treated with craniospinal radiotherapy with a boost to the primary site and areas of metastatic disease, particularly in children 3 years and older.
3. Chemotherapy is effective for most seeding tumors and has become part of the initial therapy for these tumors (neural, choroid plexus, and germ cell). By contrast chemotherapy has had limited success for most focal tumors (malignant gliomas and craniopharyngiomas).

The classification of tumors based on their histologic characteristics is important to provide prognostic information, although the unique environment of the brain makes the classification of benign versus malignant less important than for most other sites in the body. The brain and spine are critical for the control of basic autonomic response, as well as higher order function, and therefore limit the ability to obtain complete resection with a wide margin in most cases. Even benign tumors located in critical and inoperable structures may result in death if their growth cannot be stopped or slowed. Conversely many highly malignant World Health Organization (WHO) grade IV brain tumors (defined histologically)

TABLE 57-2 Common Types of Treatment for Pediatric Central Nervous System Tumors*

Type of Tumor	Method of Spread	Attempted Surgery	Type of Radiation Therapy†	Chemotherapy
Glial	Local	Yes	Focal	No‡
Neuronal	Seeding	Yes	CSI	Yes
Choroid	Seeding	Yes	CSI	Yes
Germ cell	Seeding	Yes	CSI	Yes
Cranio	Local	Yes	Focal	No

CSI, Craniospinal irradiation.

*Tumors that exhibit focal growth receive attempted resection and focal radiation therapy. Tumors that are at high risk for early dissemination are treated with focal surgery, CSI, and chemotherapy.

†Radiation therapy is often deferred in children younger than 3 years.

‡Symptomatic unresectable low-grade gliomas are treated with chemotherapy to delay radiation therapy.

that are responsive to radiation treatment (CNS germinoma) or radiation and chemotherapy (medulloblastoma) have an excellent prognosis. Because patients and their parents have preconceived notions about the importance of benign versus malignant, clarifying these terms early can be important.

The presenting symptoms for patients with CNS tumors can usually be categorized into one of two patterns: (1) direct compression of nerves or (2) obstructive hydrocephalus. The location of the tumor, histologic subtype, and age of the patient are major determinants in the length of clinical symptoms before the diagnosis is made.[111] Although dependent on the location and rapidity of growth, the time to diagnosis for many children may range from 3 to 8 months, and multiple visits to primary care providers is not infrequent.[112] For younger children who cannot verbalize their symptoms and for whom fine motor coordination, speech, and gait are still developing, even greater delays may result.

Symptoms related to the direct compression of adjacent nerves by a tumor will cause a unique constellation of symptoms that can be localized to an area as a result of the highly organized structure of the CNS.

- The posterior fossa contains the brainstem, 12 cranial nerves, and the descending and ascending fibers connecting the upper and lower aspects of the CNS, in addition to the cerebellum, which is responsible for movement and balance. Tumors in this area result in cranial nerve dysfunction such as diplopia, choking, or facial asymmetry. Tumors of the brainstem can compress the descending motor tracts, resulting in lower motor deficits. Compression of the cerebellum will lead to ataxia or dysmetria.
- The thalamus is the major relay station of coordinated function from the motor strip and other areas of the cortex. Tumors in this area will often lead to significant hemiparesis.
- The frontal lobe regulates mood and behavior and contains the motor cortex. Patients with tumors in this area will often present with changes in behavior (more aggressive or more passive), worsening school performance, or specific motor deficits (except those controlled by the cranial nerves).[113,114] In some patients, more subtle signs of frontal lobe dysfunction such as fatigue, lack of interest, or decreased energy can be mistaken for the behaviors frequent in adolescence.
- The parietal lobe possesses the centers for sensory function. Tumors in this area can often compress a specific area of the sensory cortex, resulting in a focal sensory deficit that does not follow classic dermatomal or peripheral nerve patterns.
- The hypothalamus and suprasellar regions contain the area that coordinates endocrine function (i.e., growth hormone, regulation of salts, pubertal development, and stress hormones). This area is near the optic nerves and chiasm. Tumors in this area often present as a change in growth (accelerated or delayed), hormonal dysfunction, or change in vision.
- The occipital lobe organizes and interprets vision. Tumors in the occipital lobe will present with homonymous defects in vision.
- The pineal area sits adjacent to the centers of upward gaze (supranuclear tectal or pretectal areas). Lesions in this area can result in Parinaud syndrome (paresis of upward gaze, enlarged pupils that are poorly reactive to light, and poor or limited convergence).
- The spinal cord possesses all the ascending and descending tracks for sensory and motor function to all areas innervated from that segment of the cord and below. Mass lesions in this area will reduce the motor and/or sensory activity of those areas below the lesion and can consist of motor, sensory, temperature, position, and vibration abnormalities.
- Gray matter is where neuron bodies are concentrated. Lesions in the gray matter of the frontal, parietal, temporal, and occipital lobes can result in seizure activity.[115] Although initially focal in nature, seizures can rapidly become generalized, obscuring the initial presenting focality.
- White matter tracts are the myelinated axons of neurons. Lesions in white matter tracts typically result in focal neurologic deficits that correspond to the tracts compressed.

The differential diagnosis of a new tumor of the CNS should be developed using the preceding information. Symptoms will help localize the probable site of the tumor. In turn the site will assist in developing a limited differential diagnosis of possible tumors at that site. Staging and treatment can then be considered in the context of focal versus seeding tumors. Although this exercise will not obviate the need for a definitive biopsy, it can help organize the large array of CNS tumors and ensure that appropriate presurgical planning and staging have been completed.

Obstructive Hydrocephalus and Raised Intracranial Pressure

The brain and spinal cord are supported in the cranium and spinal canal by the CSF, which is largely localized to

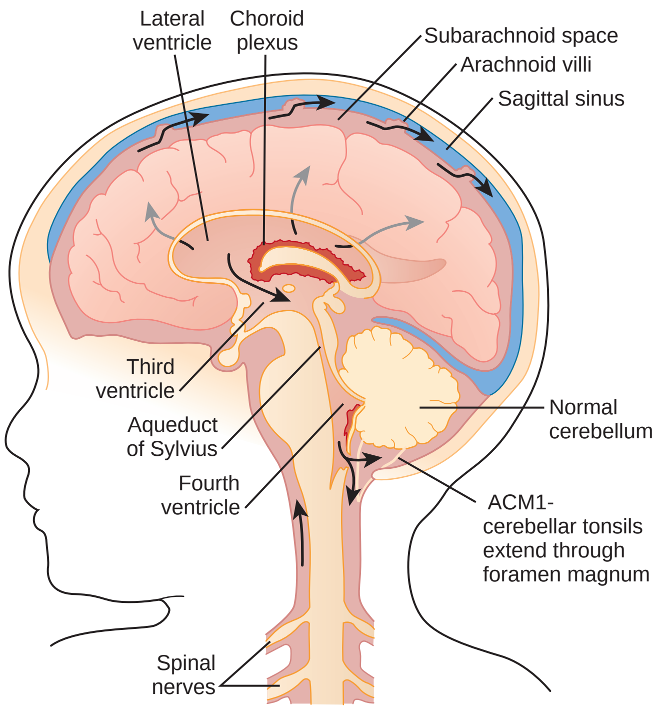

Figure 57-12 Normal flow of cerebrospinal fluid. *Blue arrows* show compression of cortex as a result of obstructive hydrocephalus. *ACM1,* Arnold-Chiari Malformation Type 1.

the subarachnoid space. CSF is initially made by the choroid plexus in the lateral ventricles and, to a lesser degree, in the third and fourth ventricles. The production of CSF is not linked to its passage from the lateral and third ventricles to the fourth ventricle and, finally, through the foramen of Magendie or foramen of Luschka, where it is eventually reabsorbed by the arachnoid villi (Fig. 57-12). The ventricles hold approximately 50 mL of CSF and, with approximately 500 mL of CSF produced each day, any failure to remove old CSF in the context of continued production will cause the fluid-filled ventricles to expand like water balloons in the closed cranium. Obstruction anywhere above the exit from the ventricles to the subarachnoid space (posterior fossa or above) will therefore result in obstructive hydrocephalus. The speed with which the accumulation of fluid occurs will in part determine the rapidity of the symptoms, as well as their severity. Obstructive hydrocephalus is considered a medical emergency because progressive expansion of the ventricular volume will force the brain to be compressed in all directions, including downward, resulting in tonsillar herniation.

The three common symptoms of obstructive hydrocephalus include headaches, often severe in nature, that are thought to arise as a result of stretching of vessels and the pial surfaces. These headaches can often be worsened by changes in body position or head motion. They can be dull, aching, or stabbing in nature. Because of the prevalence of headaches in the general population, it is their persistence and worsening in the context of other symptoms (e.g., morning vomiting and focal neurologic deficits) that usually trigger further investigation. Patients will often have vomiting (often associated with a headache), especially early in the morning upon wakening. Whether this symptom results from hydrostatic pressure changes when first getting up, resulting in compression of the area postrema, or changes in CNS homeostasis upon wakening as a result of more rapid breathing and carbon dioxide release is unknown. Unfortunately the significance of morning vomiting is often overlooked and thought to be related to school avoidance or the flu. Many patients present with prolonged histories of intermittent morning vomiting and headache, suggesting that this process can be partial and relieved by the vomiting, which itself causes raised intraabdominal pressure and equilibration of the CSF pressure gradient. A third common symptom in children with hydrocephalus is blurring of the optic discs, related to the increase in intracranial pressure (ICP). Patients often report blurring or double vision, as well as difficulty in upward gaze. These symptoms likely result from a constellation of factors, including compression of the brainstem and cranial nerves, as well as edema and swelling of the optic discs (papilledema) and pathways leading to vision. The final common symptom of obstructive hydrocephalus is the presence of lower motor deficits, likely because of compression of motor tracts within the brainstem and difficulties with balance and gait related to pressure on the cerebellum.

The symptoms of obstructive hydrocephalus differ in infants, in whom the presence of open sutures permits the head to expand. This expansion relieves the buildup of pressure and thus the associated symptoms. While their head size expands, infants may begin to show some signs of delay in gaining milestones. Careful attention to head circumference changes will help identify these infants early, independent of the cause of the obstruction.

CT imaging of the brain is a rapid method for confirming the presence of obstructive hydrocephalus. Images (without the need for contrast material) will demonstrate enlargement of the ventricles above the area of obstruction. Increasing concerns of radiation dose regarding repeat CT imaging in young children has resulted in a shift to rapid-sequence MRI vent checks.[116] These images are performed without contrast material and are not useful for assessing changes in the tumor. However they have the advantage of assessing changes in fluid within the CNS and without exposure of the child to ionizing radiation.[117,118] MRI will show large ventricles on T1- and T2-weighted images. Best seen on fluid-attenuated inversion recovery (FLAIR) sequences, the presence of a bright signal around the ventricles is suggestive of transependymal flow, which is thought to result from the backward transduction of pressure from the ventricle to the brain parenchyma (Fig. 57-13).[119] Obstructive hydrocephalus is a surgical emergency and requires urgent intervention. For posterior fossa tumors such as medulloblastoma, ependymoma, or low-grade astrocytoma, relief from obstruction can be achieved with resection of the tumor in most patients, thus avoiding the need for a separate CSF diversion procedure.[120]

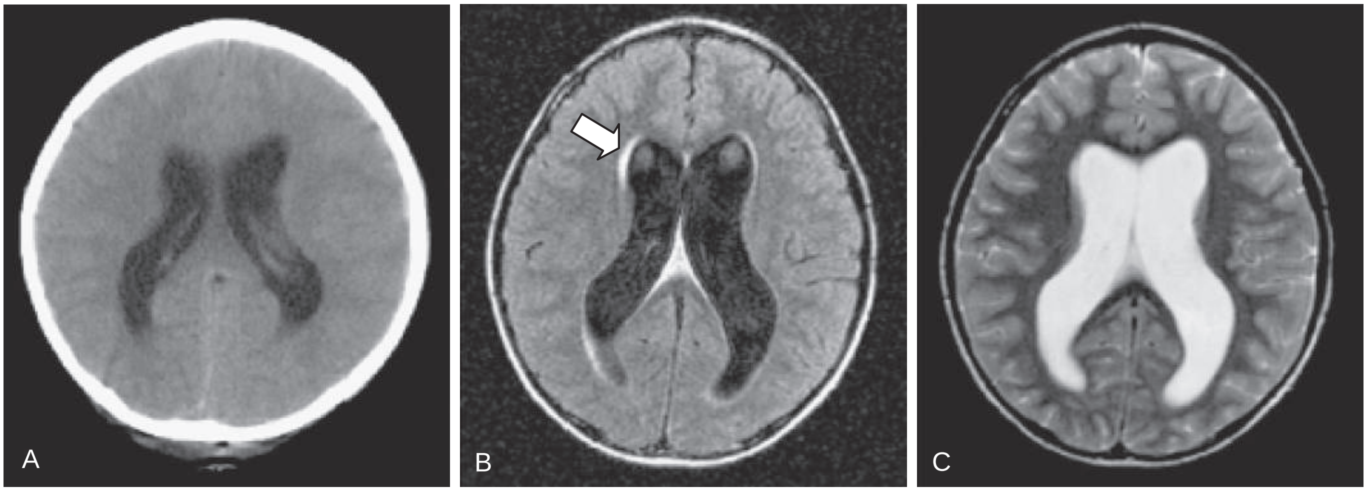

Figure 57-13 Hydrocephalus. **A,** An axial computed tomography noncontrast scan demonstrating significant enlargement caused by obstructive hydrocephalus. **B,** An axial fluid-attenuated inversion recovery image demonstrates enlarged ventricles and transependymal flow *(arrow)*, suggestive of raised intracranial pressure. **C,** An axial T2-weighted magnetic resonance image demonstrating enlarged ventricles.

IMAGING STUDIES

Neuroimaging

Imaging of brain tumors entails determining the size and site of origin of the lesion, establishing primary diagnosis, and planning treatment. Neuroimaging is critical for the appropriate placement of catheters for stereotactic biopsy, resection, planning of radiation, guided application of experimental therapeutics, and delineation of tumor from functionally important neuronal tissue. After treatment, imaging is used to quantify response and the extent of residual tumor. At follow-up imaging helps determine tumor progression and differentiate recurrent tumor growth from treatment-induced tissue changes, such as radiation necrosis.[121]

Imaging brain tumors in children presents unique challenges not encountered in adult imaging, including the need for sedation and consideration of the long-term effects on a growing child. Cranial CT and MRI remain the main modalities for the primary diagnosis of brain tumors. However several other techniques are being increasingly used in the evaluation of this patient population, including positron emission tomography (PET), MR perfusion and diffusion, and MR spectroscopy (MRS). Assessment of response in pediatrics is a critical component in the appropriate treatment of patients, as well as in identifying active regimens. Recently adult neurooncologists have adopted a new series of guidelines (developed by the International Radiologic Assessment in Neuro-Oncology Committee) to aid in better differentiating tumor progression from pseudoprogression and similarly tumor response from pseudoresponse. Although some of these adult criteria will be useful in pediatrics, the types of tumors common in the pediatric population will require some modifications to the adult approach. Currently an international working group is developing recommendations for children with brain tumors (Radiologic Assessment in Pediatric Neuro-Oncology).[122]

CT is a rapid and inexpensive modality for assessing fluid, blood, and calcification in the central CNS. As such it has typically been the first imaging procedure in children with a presumed intracranial bleed or raised ICP that might require immediate neurosurgical intervention. Other than for lesions arising from the skull vault and to assess calcified tumors, CT scans are used less frequently for routine surveillance of pediatric patients because of an increase in long-term cancer risk caused by CT imaging.[53,116]

MRI is currently the modality of choice for localization and assessment of the size of brain tumors. MRI provides valuable information about secondary phenomena such as mass effect, edema, hemorrhage, necrosis, and signs of increased ICP. In addition MRI provides excellent tissue contrast and high spatial resolution. Standard T1- and T2-weighted MRI sequences detect brain tumors with high sensitivity. Varying acquisition parameters such as T1 or T2 weighting, techniques such as diffusion- and perfusion-weighted images, and FLAIR sequences reveal a characteristic pattern of each tumor, depending on tumor type and grade.[123] Susceptibility-weighted MRI is useful for detecting areas of hemorrhage, calcifications, and increased vascularity associated with brain tumors.[124] Recently rapid-sequence MRI for the assessment of bleeds or hydrocephalus has been developed, which can avoid the radiation doses associated with CT scans and, like CT scans, can be performed without sedation, even in young children.[117,118,125] However it should be noted that these studies are limited in evaluation of the tumor burden and should only be used to assess for acute findings.

MRS can also be helpful for the initial characterization of tumors[126,127]; it can also be used to differentiate tumor tissue from other tissue in children with CNS tumors in certain circumstances.[128] MRS has continued to evolve, and the development of multivoxel and two-dimensional techniques has resulted in improved spatial resolution, thereby supplying additional information regarding tumor heterogeneity and intratumoral metabolite distribution. Although MRS is a sensitive technique, it still lacks specificity as a stand-alone technique in the clinical setting. In a recent study, brain proton MRS biomarkers were shown to predict survival of children with CNS tumors better than standard histopathology. More accurate prediction using this noninvasive technique represents an important advance and may suggest more appropriate therapy, especially when a diagnostic biopsy is not feasible.[129] In general, decreased *N*-acetylaspartate (NAA) and creatine concentrations and increased choline concentrations correlate with tumor grade. Reduction of NAA is likely because of neuronal death or damage, although the reduction in creatine is likely to be a result of changes in cell energetics. The increase in choline is believed to reflect increased membrane synthesis. Increases in lipid and lactate concentrations have been observed in some gliomas. Lactate accumulation is believed to be a result of central tumor necrosis.

Diffusion-weighted MR pulse sequences enable a quantitative and reproducible assessment of the diffusion changes, not only in areas exhibiting signal abnormality in conventional MRI but also in areas of normal signal.[130] MR diffusion using predominantly echoplanar techniques has been useful in the characterization of tissue, tumor cellularity, tumor grading, tumor response to treatment, and distinction of tissue types.[131,132] Diffusion tensor imaging (DTI) provides visualization of fiber bundle direction and integrity, with in vivo characterization of the rate and direction of white matter diffusion. DTI is useful for presurgical planning or coregistration of tractography data with radiosurgical planning and functional MRI data.[133] Fractional anisotropy using DTI may prove helpful for the assessment of treatment-induced white matter changes in children.[134,135]

The usefulness of diffusion-weighted imaging (DWI) for characterizing intracranial cystic or cystlike lesions has been demonstrated in a number of studies.[136-139] DWI has long been used to differentiate between epidermoid and arachnoid cysts.[139,140] Arachnoid cysts are characterized by free diffusion, whereas epidermoids have an apparent diffusion coefficient similar to that of brain parenchyma, thereby demonstrating restricted diffusion.[137] The usefulness of DWI in the distinction between ring-enhancing cerebral lesions such as brain abscesses, cystic or necrotic HGG, or metastasis has been shown in multiple studies during the past decade, although this differentiation continues to be a challenge.[141] The ring enhancement of a brain abscess can be indistinguishable from that of a cystic or necrotic HGG or metastasis. Other lesions that may also have a similar appearance are subacute ischemic infarction, resorbing hematoma, and demyelinating disease.[130] Abscesses demonstrate high signal on DWI and a reduced apparent diffusion coefficient (ADC) in a cystic ring-enhancing cerebral lesion.[140,141] ADC values have been assessed between tumor types; however, considerable overlap exists between certain tumor types, requiring additional evaluations.[132,142] Authors of a retrospective study of ADC values of 275 adult and pediatric brain tumors have reported a significant negative correlation between ADC and WHO astrocytic tumor grades II through IV.[142] Other comparisons included a higher ADC in dysembryoplastic neuroepithelial tumors (DNETs) than in astrocytic grade II tumors (100% accuracy) or other glioneuronal tumors, a lower ADC in malignant lymphomas compared with glioblastomas and metastatic tumors, a lower ADC in CNS PNETs compared with ependymomas, and a lower ADC in meningiomas compared with schwannomas. The ADC of craniopharyngiomas was higher than that of pituitary adenomas, whereas the ADC of epidermoid tumors was lower than that of chordomas. In meningiomas the ADC was not indicative of malignant grade or histologic subtype. DWI has also been used to obtain additional information regarding tumor type and grade. The reduction in extracellular space, as well as high nuclear-to-cytoplasmic ratios of some cancer cells, causes a relative reduction in ADC values.[131,143] In some studies overlap was seen in ADC values of HGGs and LGGs.[132] The presence of glycosaminoglycans such as hyaluronan in the extracellular space of some HGGs may decrease water content and cause a reduction in ADC values.[144] In addition, one pitfall of DWI is that high-grade tumors that may exhibit necrosis can lead to higher ADC values.[145]

DWI and proton MRS have been evaluated as diagnostic tools, and in a study of children with posterior fossa lesions in which these techniques were combined, MRI was successful in correctly identifying the histologic diagnosis in every case.[146] Although this approach does not replace the pathologic diagnosis, it demonstrates the increasing accuracy of biologic-based imaging.[147,148] Similar results have been reported for ADC analysis.[149,150] DWI may also be helpful in differentiating postsurgical changes from tumor recurrence.[148] DWI can also detect acute changes in white matter from methotrexate administration, which must be differentiated from progressive disease.[151]

Determination of the tumor margins is considered by many investigators to be extremely important for the management of brain tumors. Complete resection of tumors with minimal neurologic deficit is the ultimate goal of surgical resection. In some studies DWI has been shown to discriminate among tumor, infiltrating tumor, peritumoral edema, and normal brain parenchyma.[152,153] However other studies have not found DWI to be helpful for evaluating tumor margins.[132,154]

MR diffusion imaging has also been assessed as a biomarker for early prediction of treatment response in patients with brain tumors. Recent studies have indicated the possibility of using functional diffusion map analysis as an early biomarker for treatment response preceding decrease in tumor size.[155,156] Increasingly MR perfusion imaging is being used to evaluate cerebral perfusion dynamics by analysis of the hemodynamic parameters of relative cerebral blood volume (CBV), regional cerebral blood flow (CBF), and mean transit time. CBV is the parameter most commonly quantified in brain tumors.[157] CBV is defined as the volume of blood in a region of brain tissue, commonly measured in milliliters per 100 g of brain tissue. CBF refers to the volume of blood/unit time passing through a given region of brain tissue, measured in milliliters per minute per 100 g of brain tissue. Mean transit time refers to the average time it takes blood to pass through a given region of brain tissue and is commonly measured in seconds.[158] Perfusion imaging techniques include T2-weighted dynamic susceptibility techniques, arterial spin labeling (ASL) techniques, and T1-weighted dynamic contrast-enhanced perfusion techniques. These techniques use exogenous tracer agents, such as paramagnetic contrast material, or endogenous tracer agents, such as magnetically labeled blood (arterial water).[159] The most common method currently performed in the clinical setting is dynamic contrast-enhanced perfusion MRI with an exogenous tracer, such as gadopentetate dimeglumine. It is assumed that the tracer is restricted to the intravascular compartment and does not diffuse into the extracellular space. Imaging is performed dynamically (rapid imaging over time during a bolus injection) using echoplanar imaging–based spin echo or gradient echo sequences. It is thought that the spin echo sequences are more sensitive to capillary level blood vessels, whereas gradient echo techniques are more sensitive to the larger vessels.[160] Although gradient echo sequences are associated with more magnetic susceptibility artifacts, particularly in the posterior fossa, they are the more common of the two techniques. For young children and infants, challenges exist relating to intravenous (IV) access, smaller intravenous catheters, and limitations of the contrast medium dose.

DTI is an adaptation of DWI and is performed by acquiring diffusion data in six or more directions, enabling determination of the direction and magnitude of water diffusion. Connecting the directions of diffusion in each voxel to those of neighboring voxels using a variety of mathematical algorithms enables creation of a three-dimensional (3D) white matter tract map, termed “tractography.” This technique is used to delineate important white matter tracts affected by tumor[161] and help guide surgical resection. In conjunction with functional MRI, tractography can be used to predict possible postoperative deficits resulting from white matter tract damage.

Dynamic T1-weighted contrast imaging can be used to assess microvascular permeability (measured as the transendothelial transfer constant, or Kps) in brain tumors.[162] Kinetic modeling of the dynamic signal changes can yield estimates of regional fractional blood volume and Kps, which is an indicator of BBB disruption and correlates with angiogenesis. This technique can be successfully performed in children, and applications of this technique may be useful for monitoring antiangiogenic therapies in pediatric patients with brain tumors.[163-165] ASL is an MR perfusion technique that does not use an IV contrast agent.[166] The perfusion contrast in the image results from the subtraction of two successively acquired images, one with and one without proximal labeling of arterial water spins, with a magnetic gradient used to invert the magnetization of inflowing blood.[167] The signal-to-noise ratio, anatomic coverage, and shorter imaging time are currently better for the dynamic contrast perfusion techniques compared with ASL. However ASL may have a future role in the imaging of pediatric brain tumors, particularly because it relies on a noninvasive endogenous contrast agent.[168,169]

The use of PET and single-photon emission CT (SPECT) imaging continues to improve[170] and can be important in helping to differentiate treatment effect from tumor recurrence.[171-174] The usefulness of PET imaging is especially evident when a baseline evaluation is performed so that postoperative changes can be evaluated in the context of the pretherapy PET avidity, thus requiring consideration of nuclear imaging early in the workup of these patients.[175,176]

Standardization of neuroimaging parameters for children with CNS tumors and the testing of novel sequences that can be adapted to specific molecular inhibitors now being evaluated in this population are being developed.[130,177]

A further advance in MRI of brain tumors has occurred with the availability of intraoperative scanners. These scanners enable preoperative guidance for stereotactic biopsy and for planning tumor resection, and they provide a review of the resection site for residual tumor prior to closure of the craniotomy.[178] Intraoperative DTI has been proposed to aid in the preservation of fiber tracts and to minimize postoperative deficits.[179]

Somatostatin receptor scintigraphy has been used to differentiate the presence of residual or recurrent tumor from scar and necrosis and is better than MRI scans for a number of pediatric tumor types.[180,181] Molecular imaging is likely to play an expanding role in neurooncology as more pathway-specific inhibitors become available.

Posterior reversible leukoencephalopathy (PRES) is increasingly identified in children with brain tumors, particularly in children with episodes of hypertension. Patients present with headaches that are usually severe, mental and visual status changes, and seizures concurrent with hypertension and characteristic MRI findings, including T2 signal abnormalities.[182] MRI findings are those of vasogenic edema with T2 and FLAIR hyperintensities involving predominantly the parietal and occipital regions bilaterally (Fig. 57-14). The diffusion changes in PRES are traditionally thought to be represented by higher ADC values, consistent with vasogenic edema. Focal areas of restricted diffusion (likely representing infarction–tissue injury with cytotoxic edema) are uncommon (11% to 26%) and may be associated with an adverse outcome.[183-187] Hemorrhage (focal hematoma, isolated sulcal-subarachnoid blood, or protein) is seen in approximately 15% of patients.[188,189] The parietal and occipital lobes are most commonly affected, followed by the frontal lobes, the inferior temporal-occipital junction, and the cerebellum.[188] Lesion confluence may develop as the extent of edema increases.

The mechanism of PRES remains controversial, although the hypertension-hyperperfusion theory is favored because of the common presence of elevated blood pressure and perceived response to hypertension management. Key issues remain problematic, including PRES in normotensive patients with pressures rarely reaching autoregulatory limits, and brain edema that is lower in patients with severe hypertension. Hypertensive

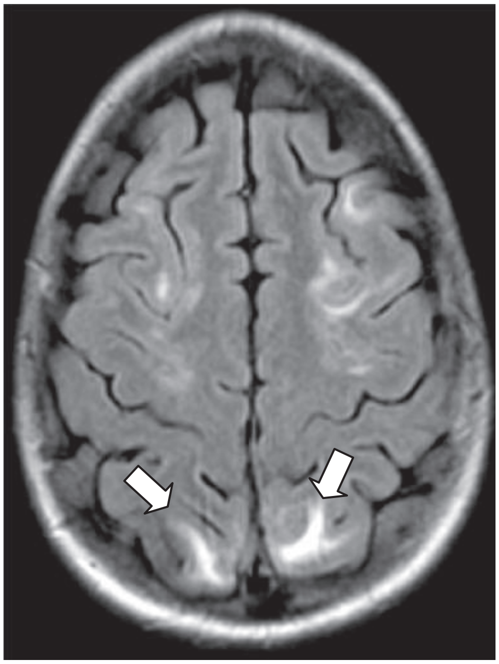

Figure 57-14 An axial fluid-attenuated inversion recovery image in a patient after radiation therapy with new-onset seizure and hypertension with bilateral hyperintense signal in the occipital lobes *(arrows)*. Also note increased signal to a lesser extent in the frontal lobe.

encephalopathy animal models do not reflect the systemic toxicity that is present, and hyperperfusion has not conclusively been demonstrated in patients.

Intracranial vasospasm has been seen with conventional and MR angiography, suggesting vasospasm as a possible pathophysiologic mechanism for the observed findings.[190] MR DWI was instrumental in establishing and consistently demonstrating that the areas of abnormality represent vasogenic edema. Prompt treatment with antihypertensive therapy or discontinuation of immunosuppressive agents can lead to complete recovery in some cases. However, if untreated, permanent neurologic deficits or even death may occur as a result of cerebral infarctions or hemorrhages,[191] and 20% to 40% of patients with PRES can be normotensive.[192,193] PRES can be associated with a number of inciting events, including chemotherapy, radiation therapy, and antiangiogenic drugs.[194] This latter group of drugs may cause PRES as a result of their direct effect on vascular endothelial growth factor (VEGF) and raised blood pressure. Rapid recognition of this entity is critical to prevent permanent damage from occurring.

Surveillance Imaging

The role and usefulness of surveillance imaging for patients with a brain tumor remain controversial and depend on a number of factors, such as the age of the patient, histology of the tumor, time from diagnosis, and type of treatment. For example, in one study only nine of 318 imaging encounters identified an asymptomatic recurrence.[195] Other studies have demonstrated the cost-effectiveness of surveillance imaging,[196] recognizing that decisions are often made on the basis of insurance coverage. A common practice has been imaging every 3 months while the patient is undergoing therapy (to assess continued response while undergoing therapy), and then every 3 months for the first year after the completion of therapy. Beginning in the second year, scans are performed every 6 months for a year and then annually afterward. With time the risk of tumor recurrence will go down, although the risks of radiation-induced vasculopathy and second tumors begin to increase. Modification of these guidelines for children with tumors at low risk of recurrence (e.g., completely resected craniopharyngioma or low-grade astrocytoma) or those who did not receive radiation therapy can be made on a case-by-case basis.

NEUROPATHOLOGY

The neuropathologic classification of pediatric brain tumors has evolved greatly during the past century. Categorizing tumors is helpful to guide therapy and estimate prognosis. A number of outstanding reviews on the classification of CNS tumors have been written.[197-206] When attempting to determine the treatment and/or prognosis of a tumor based on published reports or meeting abstracts, the classification schema used in those reports will become critical before applying this information to other patients.

Most current classification systems are based on the pioneering work of Cushing and Bailey almost 100 years ago. The major premise of this approach was to define tumors by their presumed cell of origin and cell lineage based on morphologic similarity to normal immature or mature brain cells. This system was adapted by Kernohan when he proposed that certain tumors, especially those with a glial appearance, such as astrocytomas, ependymomas, and oligodendrogliomas, could be further classified by the degree of anaplasia, which related to prognosis. Most current systems now use these two criteria—presumed cell lineage and degree of anaplasia—as the primary basis for classification of adult and pediatric CNS tumors. In spite of the usefulness of this classification schema, it is becoming progressively clear that most brain tumors do not derive from mature cell types but rather from primitive precursors or stem cells that can differentiate down many different pathways, obscuring the cell lineage. In comparison with their adult counterparts, pediatric brain tumors are exceptionally diverse in their morphologic appearance and therefore represent a particular challenge for classification by morphologic criteria alone. This diversity likely stems from the fact that pediatric brain tumors are derived from a wide spectrum of proliferative cell types at many developmental stages not present in adult brains.

Significant advances have been made in the field of neuropathology. The WHO classification of CNS tumors has been recently revised, with a number of important modifications based on histopathologic recognition of new pediatric brain tumors.[207] A synopsis of the WHO 2007 classification system is provided in Table 57-3. Increasingly the field has begun to include use of molecular alterations for many tumors and the use of highly specific immunohistochemical markers.[198-201,206,208-212] When

TABLE 57-3 Simplified World Health Organization Classification of Pediatric Central Nervous System Tumors

Type	Subtype	Example(s)	Grade
Glial tumors	Astrocytic tumors	Pilocytic astrocytoma	I
		Subependymal giant cell astrocytoma	I
		Pilomyxoid astrocytoma	II
		Pleomorphic xanthroastrocytoma	II
		Diffuse (fibrillary) astrocytoma	II
		Anaplastic astrocytoma	III
		Glioblastoma multiforme	IV
		Gliosarcoma	IV
		Gliomatosis cerebri	III-IV
	Oligodendroglial tumors	Oligodendroglioma	II
		Oligoastrocytoma	II
		Anaplastic oligodendroglioma	III
		Anaplastic oligoastrocytoma	III
	Ependymal tumors	Subependymoma	I
		Myxopapillary ependymoma	I
		Ependymoma	II
		Anaplastic ependymoma	III
Neural/embryonal tumors		Medulloblastoma	IV
		Pineocytoma	I
		Pineal parenchymal tumor of intermediate differentiation	II-III
		Papillary tumor of the pineal region	II-III
		Pineoblastoma	IV
		Primitive neuroectodermal tumor (medulloepithelioma, ependymoblastoma)	IV
		Atypical teratoid-rhabdoid tumor	IV
Choroid plexus tumors		Choroid plexus papilloma	I
		Atypical choroid plexus papilloma	II
		Choroid plexus carcinoma	III
Germ cell tumors	Germinoma		III
	Nongerminoma	Embryonal carcinoma	III
		Yolk sac tumor	III
		Choriocarcinoma	III
		Mature teratoma	0
		Teratoma	I
		Immature teratoma	III
		Teratoma with malignant transformation	III
Craniopharyngioma	Craniopharyngioma	Adamantinomatous	I
		Papillary	I
Other	Mixed glial neuronal tumor	Ganglioglioma	I
		Gangliocytoma	I
		Anaplastic ganglioglioma	III
		Dysembryoplastic neuroepithelial tumor	I
		Desmoplastic infantile astrocytoma	I
		Central neurocytoma	II
		Extraventricular neurocytoma	II
	Neuroepithelial	Astroblastoma	—
	Nerve tumors	Schwannoma	I
		Neurofibroma	I
		Malignant peripheral nerve sheath tumor	II-IV
	Meningeal	Meningioma	I
		Atypical meningioma	II
		Anaplastic meningioma	III
		Hemangioblastoma	I

combined with immunohistochemical analysis and the increasing use of cytogenetic classification and molecular profiling, the classification of tumors continues to become more reproducible and predictive of clinical outcomes. A simplified overview of the chromosomal abnormalities associated with pediatric brain tumors is presented in Table 57-1. For many large consortium-based studies in both Europe and North America, molecular profiling of tumors to ensure proper classification is now required, especially for medulloblastoma and ATRTs.

The immunohistochemical patterns used to classify CNS tumors require considerable experience on the part of the neuropathologist, as well as appropriate control subjects. Most markers lack specificity and can be identified in a wide array of histologies, requiring correlation with other clinical or molecular data.[213] Common

TABLE 57-4 Immunohistochemical Markers of Pediatric Central Nervous System Tumors

Marker	Tumor
Glial fibrillary acidic protein	Astrocytoma, oligodendroglioma, ependymoma, choroid plexus papilloma, PNET, ATRT
Synaptophysin/NeuN	PNETs, ganglial tumor, neurocytoma
MIB1/Ki-67	Measures all cells not in G0
Mitotic rate	Measures cells in mitosis
Neurofilament proteins	Ganglial tumor, PNET, neurocytoma, subependymal giant cell tumor, ATRT
S-100 and neuron-specific enolase	Normal and neoplastic glial and neuronal in origin
Retinal S-antigen	Pineal parenchymal tumor, PNET, retinoblastoma
Desmin	Muscle tumor, teratoma, PNET
Smooth muscle actin	Muscle tumor, ATRT
Cytokeratin	Chordoma, choroid plexus tumor, meningioma, some malignant gliomas, nongerminomatous germ cell tumor, PNET, ATRT
Epithelial membrane antigen	Meningioma, ependymoma, teratoma, ATRT
Vimentin	Mesenchymal tumor, meningioma, sarcoma, melanoma, ependymoma, astrocytoma, chordoma, schwannoma, PNET, ATRT
Alpha-fetoprotein	Embryonal carcinoma, endodermal sinus (yolk sac) tumor
Human chorionic gonadotropin	Germinoma, choriocarcinoma
Placental alkaline phosphatase	Germ cell tumor
INI-1	ATRT

ATRT, Atypical teratoid/rhabdoid tumor; *PNET,* primary neuroectodermal tumor.

markers used to classify pediatric CNS tumors are provided in Table 57-4. Four commonly used immunohistochemical markers are the oligodendrocyte lineage transcription factor 2 (OLIG2)[214] and glial acidic fibrillary protein (GFAP), which stain glial cells (Fig. 57-15); synaptophysin, which stains neurons (Fig. 57-16); and Ki-67, which stains cells that have left G0 cell cycle and are at some stage of cellular division (Fig. 57-17).

TREATMENT STRATEGIES

Neurosurgery

The neurosurgeon is often the first of the specialized team of caregivers called to see a child with a brain tumor, with

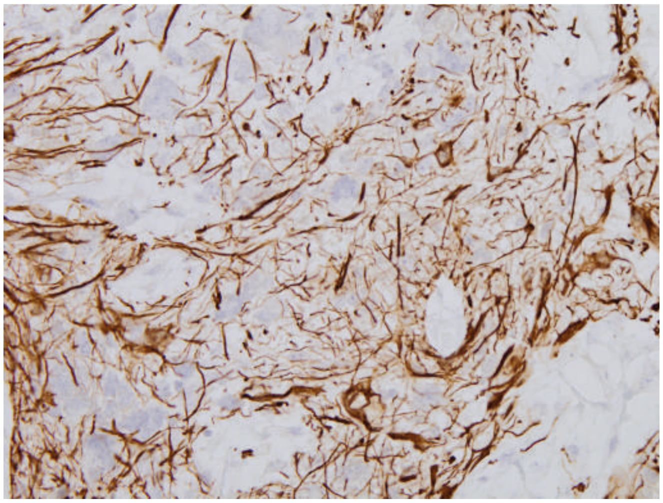

Figure 57-15 Glial acidic fibrillary protein staining of astrocytic cells in a child with glioblastoma multiforme (×400).

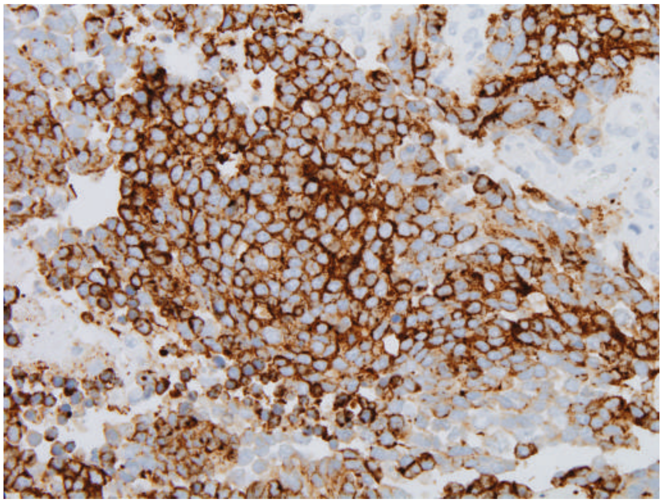

Figure 57-16 Synaptophysin immunohistochemical staining of medulloblastoma (×400).

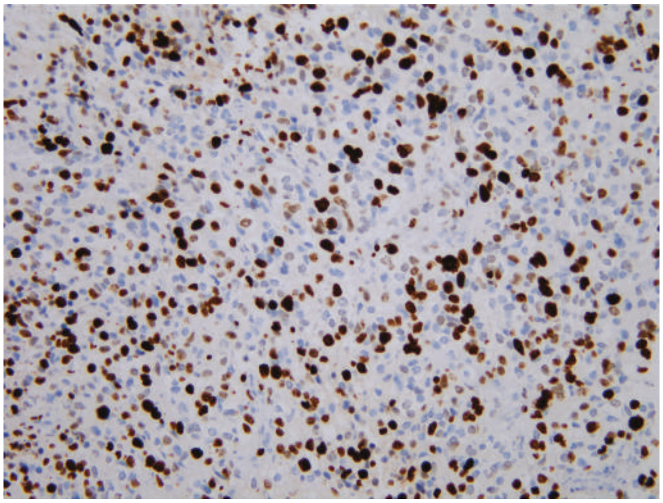

Figure 57-17 Ki-67 immunohistochemical staining in glioblastoma multiforme (×200).

the call frequently coming from the emergency department or radiology department. The initial evaluation consists of acute management—that is, assessment of the patient's clinical condition with respect to neurologic stability and the possibility of acute neurologic decompensation requiring immediate intervention, and subsequent to that the development of a plan that includes surgical interventions geared toward obtaining tissue for pathologic diagnosis, resection of tumor as part of the overall management of the tumor, and dealing with the secondary effects of the tumor.[215-217]

In the field of neurosurgery remarkable advances have occurred in technology, from intraoperative microscopes, robotics, and computer-assisted navigation to intraoperative MRI, endoscopic techniques, and minimally invasive techniques.[218,219] Each of these advances has been instrumental in reducing the morbidity of neurosurgical procedures while ensuring maximal surgical resections.

Acute Management Issues

Hydrocephalus. Hydrocephalus is the most common clinical presentation of posterior fossa brain tumors, which are the most common pediatric brain tumors. Historically the initial evaluation of children suspected of harboring a posterior fossa brain tumor has been via CT scan. However with improved technologies and more recent concerns regarding the long-term effects of radiation exposure, there is a trend toward less utilization of CT scans. If possible the initial assessment should be an MRI of the brain, which can provide the dual information regarding the brain tumor and the extent of hydrocephalus. The cause of the hydrocephalus is obstruction to the CSF flow as a result of the tumors in and around the fourth ventricle. The evaluation should consist of assessing the severity of the hydrocephalus (via the presence of periventricular capping/edema and tonsillar herniation) and the need for immediate intervention. High-dose steroids will often produce significant relief in symptoms as peritumoral edema is suppressed, and they are often utilized as a temporary measure for symptom relief. In infants, hydrocephalus can be asymptomatic and only evidenced by a rapidly enlarging head circumference. Supratentorial brain tumors can also produce hydrocephalus by causing mass effect on the ventricles, as well as by obstructing CSF flow through the ventricular system. Patients with suprasellar tumors can also have inadequate cortisol production or electrolyte disturbances, which need to be addressed as quickly as possible and often in concert with preparation for surgery.[220]

Raised ICP is a medical emergency. Immediate relief can be accomplished by temporary placement of a catheter (drainage tube) in the ventricles, although this step is rarely needed, primarily because of the fact that steroids in the preoperative period followed by surgery to remove the tumors within 24 to 48 hours after diagnosis usually relieves the obstruction. Permanent techniques of hydrocephalus treatment include the placement of a ventriculoperitoneal (VP) shunt that drains CSF around the obstruction into the peritoneal space via a permanently implanted tube and more recently via an endoscopic third ventriculostomy (ETV).[221,222] The latter has become the treatment of choice in the management of obstructive hydrocephalus and is not associated with the long-term complications of shunt revisions and infections.[223] Most pediatric centers with sufficient expertise now routinely perform ETVs as the primary management of hydrocephalus in children with brain tumors.[224] In addition the overall incidence of shunting for brain tumors has decreased during the past two decades.[225,226] Like all complex procedures, rare but significant neurologic risks are associated with this procedure in approximately 1% of cases.[227] The possibility of closure of a third ventriculostomy and resultant acute hydrocephalus requires long-term follow-up with neurosurgery, as with all children who have had placement of shunts for the management of the hydrocephalus.

Visual and Endocrine Evaluation. Children with tumors in the sellar and suprasellar area can present with blindness, which rarely can be acute in onset. In those circumstances, although extremely rare, it is possible to obtain some recovery of vision by immediate treatment of the tumor. If a large mass or cyst is causing compression, acute drainage in conjunction with steroid administration can lead to some recovery of vision. Tumors in this location can also interfere with endocrine function and may lead to electrolyte disturbances and decreased steroid production, and these effects can be critical if they are unrecognized, especially if acute surgical intervention is indicated.

Surgical Management

Surgical management after treatment of hydrocephalus consists of obtaining tissue for diagnosis and resecting the tumor. The decision to perform these procedures depends on the location of the tumor, the known biology, and the goals of treatment management.

Certain tumors do not require routine biopsy or attempted resection at diagnosis (e.g., diffuse pontine gliomas, classic optic pathway tumors in children with NF-1, and some suprasellar or pineal lesions with positive serum or CSF tumor markers). Tectal gliomas are rare tumors centered in the tectum with a classic radiographic appearance and presentation of hydrocephalus and, rarely, neurologic deficits. Their management consists solely of treatment of the hydrocephalus via ETV and radiographic and clinical follow-up.

The leading factor in the outcome of a child with a brain tumor is not the presenting symptoms, age of the child, or the final disease. Rather it is the experience of the neurosurgeon performing the operation and the number of similar procedures performed during the prior few years.[228] With increasing cure rates in children with CNS tumors, careful consideration of the neurosurgical morbidity, which can often be lifelong, needs to be taken into account while a treatment plan is developed.[229]

Advances in Surgical Techniques. Recent advances in image-guided neurosurgical techniques have been considerable. Endoscopic procedures provide minimally invasive techniques to address not just obstructive hydrocephalus but also biopsy or resection of intracranial masses, with minimal morbidity in experienced hands.[230] New techniques using intraoperative ultrasound have been developed and are being used in pediatric patients.[231] 3D laser-guided maps can assist in the orientation and surrounding environment of the tumor during a procedure. More recently intraoperative MRI facilities now allow surgeons to use MRI procedures with the same magnet strength as that used for diagnostic imaging while operating.[232] Real-time MRIs can assist the neurosurgeon in the detection of residual disease or hemorrhage before closure of the resection site.[233]

The surgical approach used by the neurosurgeon will depend on a number of factors that must balance the need for diagnosis with the potential risks of operating in a given area.[234] While the relative risks of general anesthesia and neurosurgical procedures continue to diminish with improving techniques, it is now common to perform staged operations in which a limited resection is performed to confirm the diagnosis. Based on the pathologic results obtained, decisions about more complicated or risky surgery can be considered for lesions in which complete resection is a critical component of improved outcome and can be deferred in lesions in which additional resection would not significantly alter prognosis but could cause significant morbidity. Specialized techniques such as endonasal endoscopic approaches can allow a minimally invasive approach, with excellent outcome in centers that have expertise in this approach.[235]

The need of neurosurgeons to be aware of the evolving treatment strategies for children reinforces the role of the multidisciplinary team. During the past 5 years this need has become even more important, because many pediatric brain tumors now require molecular classification to guide therapy. For example in spite of their similar appearance, the treatment of posterior fossa medulloblastoma now differs significantly from posterior fossa ATRT. Treatment on national protocols therefore requires submission of fresh-frozen material obtained at the time of surgery for proper stratification on the basis of therapy protocols. As our molecular classification of pediatric brain tumors expands and newer and better molecular inhibitors of specific pathways become available, the role of the neurosurgeon and neuropathologist in ensuring the proper processing of these samples will continue to expand.

Perioperative Issues. A number of factors must be considered for a child after a tumor-based procedure has been completed. The rate of weaning steroids after an operation will depend on many factors, including the histology, degree of resection, postsurgical edema, and patient status. Although most patients can be weaned off steroids rapidly after an operation, it is important that the members of the team have a coordinated structure so that as children pass from neurosurgical care to the radiation therapist or oncologist, overall management of these issues is seamless. A similar discussion holds true for anticonvulsant agents. Whereas many patients will receive preoperative or perioperative anticonvulsant therapy, most can be weaned rapidly, and communication among team members will therefore be required.

Seizures can be a presenting symptom for many patients with brain tumors or a result of electrolyte disturbances in the perioperative period. Management includes anticonvulsant agents and surgical resection geared not only toward the tumor but also toward dealing with the seizures. Intraoperative electrocorticography is particularly useful in the management of temporal and frontal lobe tumors with seizures and requires a multidisciplinary approach, which can lead to excellent overall outcomes. Choices of antiepileptic drugs (AEDs) are important because some may interfere with metabolism of chemotherapeutic agents, which requires a comprehensive approach toward the management of the patient's seizures and tumor.

Hyponatremia is a common problem that can occur after neurosurgical intervention and requires immediate recognition.[236] Two common conditions, both resulting in hyponatremia but needing different interventions, can occur. Cerebral salt wasting (CSW) occurs because of excess renal loss of sodium with volume depletion and has been associated with abnormally high atrial natriuretic peptide or brain natriuretic peptide levels, which block all stimulators of zona glomerulosa steroidogenesis, resulting in mineralocorticoid deficiency.[237] CSW usually occurs 1 to 2 days after neurosurgical intervention, and patients typically demonstrate polyuria, dehydration, a serum sodium level less than 130 mEq/L, and excess urine sodium or urine osmolarity. Duration of CSW was 1 to 9 days in a study of 12 pediatric patients.[238] CSW is generally treated with salt repletion, although fludrocortisone supplementation has also been successful.[239] Syndrome of inappropriate diuretic hormone (SIADH), by contrast, results when water is preferentially retained, causing dilution of serum sodium. Patients present with hyponatremia and an elevated urine sodium level.[240] The major clinical difference between CSW and SIADH is that in the former, dehydration is common, whereas in SIADH, symptoms of dehydration are lacking. SIADH is treated with water restriction. CSW was much more common than SIADH in one study of 30 patients.[241]

Posterior fossa syndrome (or cerebellar mutism syndrome) is a complex and heterogeneous disorder that tends to occur 24 to 48 hours after resection of a posterior fossa tumor,[242] usually medulloblastoma, ependymoma, or low-grade astrocytoma. Posterior fossa syndrome will develop in up to 25% of patients undergoing surgical resection in the posterior fossa and, in most patients, it will be severe.[242] The pathophysiologic basis for this syndrome is unclear, with many hypotheses proposed. It is likely related to pressure effects on the deep cerebellar nuclei and is more frequently associated with large tumors extending into those areas. Gross total resection (GTR) of most posterior fossa brain tumors is associated with better long-term outcomes, and it is thought that the more aggressive surgical resections for those reasons are associated with the perceived increase in the frequency of this syndrome. The exact clinical patterns of posterior fossa syndrome can vary among patients both in constellation and severity. Usually the disorder includes loss of speech in patients who were capable of talking immediately after surgery. Other symptoms include irritability, which may relate to difficulties in communication, emotional withdrawal, and motor difficulties with ataxia.[242] In a review of 450 children from two large Children's Cancer Group (CCG) protocols for high-risk and standard-risk medulloblastoma, 107 patients (24%) had posterior fossa syndrome. It was classified as severe in 43%, moderate in 49%, and mild in 8%. As with many neurologic insults, most patients demonstrated significant improvement, although neurologic abnormalities persisted in a large proportion of patients.[243] No uniform diagnostic criteria exist for posterior fossa syndrome, and radiologic imaging with SPECT has failed to define a specific controlling neurologic region.[244]

Venous thrombosis in adults with brain tumors is common, especially when compared with adults undergoing operations for causes not related to brain tumors,[245,246] and typically requires therapy. A similar predilection to significant symptomatic thrombosis in children with CNS tumors has not been identified.[247] Because of the risks of spontaneous hemorrhage in patients taking anticoagulants, their routine use is discouraged for pediatric patients.[248] When thromboses in this patient population are identified, other precipitating factors such as the presence of a central venous access device[247] are usually evident.[249] CNS hemorrhage is rare in pediatric patients undergoing tumor resection. Use of recombinant factor VIIa has been used successfully when bleeding was difficult to control.[250]

Long-Term Follow-Up

Long-term follow-up is extremely important because neurosurgical sequelae of the treatment of brain tumors exist. The management of hydrocephalus is lifelong, and all survivors of childhood brain tumors who have treated hydrocephalus should undergo frequent evaluations by a neurosurgeon and radiographic evaluation of the patency of the ETV (via specialized MRIs) or of their shunt systems.

A relatively rare but significant complication of radiation therapy and surgery for tumors in the sellar/suprasellar area is moyamoya disease. This condition is manifested by the development of occlusive vascular disease at the base of the skull with subsequent ischemic events and stroke. The management includes surgical revascularization, which is effective in stopping the clinical symptomatology and preventing new ischemic events and is performed in centers with specialized interest in this condition and expertise in the surgical procedure.

Radiotherapy

A detailed section on the fundamentals of radiation oncology is included elsewhere in this text (see Chapter 48). The primary goal of this brief discussion is to focus on radiation therapy issues that are specific to pediatric neurooncology.[251] An understanding of the basic principles of radiation therapy is critical because it remains one of the most effective, albeit toxic, therapies for this patient population.

Like chemotherapy, radiation therapy targets dividing cells, one of the hallmarks of cancer therapy. Unlike chemotherapy, however, delivery of radiation therapy is not limited by the BBB. The biologic effects of ionizing radiation are the result of damage to cellular DNA, primarily through irreparable double-strand breaks. Photon radiation can cause damage through direct interaction with DNA or through the formation of free radicals, which damage the DNA. Charged particles can cause damage through direct interactions with the nucleus. This damage results in complex cascades of molecular events, affecting cell cycle checkpoints, apoptosis, DNA damage response, and DNA repair. Tumor cells have lost the regulation required to repair DNA damage before entering cell replication. In contrast normal adjacent cells that receive radiation therapy will repair the damage between fractions. After weeks of continued radiation therapy, normal cells will have repaired themselves, although the repair process is not perfect and accounts for the toxicity to normal brain caused by radiation therapy. Tumor cells, on the other hand, will have accumulated significant damage, leading to cell death. The concept of fractionation is the hallmark of radiation therapy.

Technical Aspects of Radiation Therapy

Radiation therapy technology has advanced continually since the discovery of x-rays. The most commonly used modalities in the treatment of CNS tumors are photon radiotherapy and proton radiotherapy. Both these forms of irradiation provide the same treatment dose to the tumor tissue, and therefore their differences are not related to efficacy. Rather the differences in the therapeutic beams and the physical properties associated with them result in different dose distributions. The major clinical difference between the two techniques relates to potential toxicities to the normal brain.

Photon Therapy. Photons are packets of high energy that enter tissue, depositing their energy as they pass through both normal tissue and the tumor, eventually exiting the brain. The presence of an exit dose is one of the major differences between this modality and proton therapy. The generation of photon beams is easily achieved with a large array of commercially available machines and, with more than 60 years of clinical experience, photon radiotherapy remains the most widely used form of radiation therapy. Significant advances in this modality have occurred through the development of better imaging (MRI and functional imaging such as PET and metaiodobenzylguanidine), planning algorithms, and machine delivery that has allowed the radiation oncologist to target tumors more accurately and to minimize the dose delivered to normal tissue.

Opposed Lateral Fields. Used largely before 1990, opposed lateral fields typically rely on two wide beams, usually one from the left and the other from the right. This approach is no longer considered the standard of care in children with a brain tumor because of excessive toxicity to normal brain tissue. At a minimum conformal fields should be used.

Conformal Radiation Therapy. The conformal radiation technique uses the principle of tumor volume definition through MRI and CT scans. In the treatment of CNS tumors, the anatomic localization of the bony structures of the skull using CT scans are fused to the MRI with specialized fusion software. This technique allows accurate tumor definition and submillimeter accuracy in treatment. Radiation therapists choose beam placement to maximize tumor coverage while avoiding normal brain tissue. With 3D conformal radiation therapy, conformal beams are used to shape the dose delivered to the target, and wedges or compensators can be used to optimize the dose distribution. With 3D conformal radiation therapy, variable field weighting and use of different energies (higher beam energies are more penetrating) are additional tools that enable optimization of the dose distribution. With the development of more rapid and powerful computers, the ability to generate a large number of different beam orientations has allowed for diffusion of the radiation dose over normal tissue, thus reducing long-term damage while ensuring complete coverage of the tumor volume.[252]

Stereotactic Radiotherapy. Stereotactic radiotherapy is a further improvement on 3D conformal therapy by ensuring improved head immobility so that beam configuration may be further reduced without having to worry about head position and tumor location.[253] In the normal delivery of the radiation beam, some head movement may occur; therefore, the target volume must be expanded in all directions to ensure that at no time is part of the tumor outside the targeted area. To overcome this difficulty, a series of techniques have been developed that use head immobilization to ensure less head movement and consequently smaller target volumes. Options for such immobilization include frames bolted to the skull and then fixed to the radiation device, which is the standard procedure for stereotactic radiation surgery (discussed later). The major limitation of this procedure, however, is that radiation therapy is delivered over approximately 6 weeks, and bolting screws into the skull for this length of time is not practical. A second option is the use of a head mask made for each patient, which fits around the face and skull and can sometimes use the ear canals or palate to ensure exact and reproducible fits. A new development is the use of real-time CT scans that constantly reevaluate the position of the skull, with computer software that corrects for changes in head position to reset the beams accordingly. In children the additional dose of radiation therapy from CT scans is not trivial and needs to be considered in the choice of method.

Intensity-Modulated Radiation Therapy. Intensity-modulated radiation therapy (IMRT) gives radiation therapists the opportunity to modulate the intensity of a radiation beam so that instead of uniform dosing throughout a volume, areas of decreased intensity may spare critical structures.[254] For example if a critical nerve runs through or adjacent to a tumor, IMRT allows the radiation therapist to spare the middle, like a doughnut, while still treating the entire surrounding tumor. IMRT is a device that fits onto the gantry of a radiation machine and moves small metal slots in and out of the beam path as it moves in arcs to deliver the required fields. Large metal (macroleaf) and small metal (microleaf) pieces are available. The microleaf collimators allow for a more refined shaping of the field. An important limitation of this technique is the development of hot spots in areas within the field. As a general rule this technique can be added to 3D conformal and stereotactic radiation therapy treatment plans.

Stereotactic Radiosurgery. Stereotactic radiosurgery (SRS) techniques (e.g., gamma knife, cyber knife, or X-knife) use a single fraction (or occasionally several fractions) rather than the prolonged treatment courses that are standard with radiation therapy. As the names imply in these techniques, all develop a focused beam of energy that covers a tight volume and causes the cells within the volume to die.[255] Unlike traditional radiation therapy, in which normal cells recover between successive doses while tumor cells do not, the principle for this technique is similar to focusing sunlight with a magnifying glass to burn a small area. Because of the significant toxicities possible with a technique designed to kill a targeted area, a specific volume that excludes normal adjacent structures is critical. To achieve this requirement, after induction of general anesthesia, the head is often bolted into a metal head frame, and then the metal frame is bolted to the radiation device. In this way no additional or unintended movement can occur that would result in the targeted beam missing part of the tumor and damaging uninvolved adjacent normal brain tissue. New methods that can avoid the need for fixed head localization are being developed.[256]

Proton Radiotherapy. The use of proton beam radiation therapy as an alternative to high-energy x-rays (photons) has the potential to limit some of the late effects of radiation therapy by reducing the exposure of normal tissue to the radiation.[257,258] Physically, photon beams deliver their maximum radiation dose near the surface, followed by a continuously reducing dose with increasing depth. Tissues outside the target area receive an exit dose of the radiation beams. For example when a single posterior field is used to treat the spinal axis, critical organs along the path such as the heart, lung, bowel, and ovaries may receive significant exposure. In contrast in proton beam radiotherapy, while the charged particles—namely, protons—move through tissue, they ionize particles and deposit their radiation dose along the path. The maximal dose, called the Bragg peak, occurs shortly before the point of greatest tissue penetration, which is dependent on the energy of the proton beam. Because the energy can be precisely controlled, the Bragg peak can be placed within the tumor targeted to receive the radiation dose. Because the protons are absorbed at this point, normal tissues beyond the target receive little irradiation.[259] Proton beam radiotherapy is becoming more readily available but remains a more limited and costly modality. Children most likely to benefit from proton beam treatment are those with favorable or curable brain tumors such as craniopharyngiomas, medulloblastomas, LGGs, ependymomas, and GCTs. With the increasing complexity of radiation planning, a dedicated pediatric radiation oncology team is required to ensure appropriate care for the pediatric patient.[260-262]

Toxicity of Radiation Therapy

Even with the significant advances in the highly precise delivery of radiation therapy, a number of circumstances limit its usefulness for children. Humans achieve their maximum number of brain cells shortly after birth. From that time forward, a steady loss of cells continues throughout life. While we age our neurocognitive development is related to the development of new connections and interactions between cells, not the addition of cells. For reasons that are poorly understood, irradiation can affect not only the proliferation of new cells in infancy but also the ability of cells already present to form or maintain connections in children and adolescents.

Late effects of radiotherapy in the treatment of children with brain tumors include neurocognitive sequelae, ototoxicity, hormonal dysfunction, vascular complications, growth disturbance, and secondary malignancies.[263-273] The severity of these effects depend upon many factors. The three major factors that determine the severity of the impairment after radiation therapy are the age of the patient, the volume of the brain to be irradiated, and the dose of radiation therapy required.

1. *Age*. Because the age of the patient at diagnosis is not mutable, simply withholding radiation therapy until a child has had an opportunity to grow older would reduce the long-term morbidity, but this approach may allow a tumor to recur. As such, the decision between accepting toxicity or foregoing efficacy is not uncommon in pediatric practice.
2. *Volume*. Although neurocognitive development is most active from birth until the age of 3 years, significant development occurs up to the age of 10 years and even into adulthood, which implies that radiation therapy to large parts of the brain can cause detrimental effects on cognition throughout life. Because the volume of brain to be irradiated is determined by the extent of tumor spread, radiation therapists must treat the required volumes with all the associated long-term morbidity or reduce the volume to be treated with a corresponding reduction in the efficacy that radiation provides.
3. *Dose*. The third factor related to radiation toxicity is the dose used. Because most brain tumors require the use of maximal tolerated doses to have a significant clinical impact on outcome, reducing the dose would again require a tradeoff between toxicity reduction and efficacy reduction.

Further discussion of the toxicities of radiation therapy is found in Chapter 47.

Chemotherapy

The approach and use of chemotherapy, like radiation therapy, does not differ significantly for most children with brain tumors when compared with children with other cancers. Similarly the effects of antiseizure medications on chemotherapy mirror those of other patient populations, and agents susceptible to altered metabolism by enzyme-inducing anticonvulsants, such as irinotecan, require appropriate dose adjustments or a switch to a nonenzyme-inducing anticonvulsant.[274-276] This requirement has resulted in the development of many pediatric treatment regimens modified from adult studies.[277] The increasing recognition of the unique nature of pediatric tumors in general and pediatric brain tumors specifically has led to the development of pediatric-specific preclinical models of cancer.[278-281] Incorporation of information from these models is likely to be slow as different combinations of chemotherapy, biologic therapies, and radiation therapy undergo evaluation. The need for drugs to cross into the brain raises questions about agents that showed no activity in prior clinical trials. Although the routine approach was to discard such agents as inactive, the ability to modify such agents to improve their CNS penetration has resulted in the need to retest some of these chemotherapeutic classes.[282-284]

Blood-Brain Barrier

The BBB results from the tight junctions of endothelial cells and astrocytic projections surrounding the brain that limit the penetration of substances, especially infections and inflammatory responses, from gaining access to the CNS. A slightly different barrier exists between the blood and CSF (called the blood-CSF barrier), although the primary role of the two systems remains the same—to isolate the brain from the entry of as many foreign chemicals and pathogens as possible.

While tumors develop, they grow and invade normal structures, which can disrupt the BBB. Tumors also need to secure a blood supply, which can be achieved through the secretion of a large number of cytokines, of which the best characterized is VEGF. Before its discovery in stimulating angiogenesis, this molecule was initially discovered as vascular permeability factor (VPF) because of its ability to open up endothelial junctions, allowing for changes in fluid shifts. The secretion of VEGF (VPF) by tumors is responsible for significant peritumoral edema and leakage of the BBB. For reasons that remain poorly understood at present, many tumors, or areas within tumors, do not demonstrate disruption of the BBB, making their detection on contrast-enhanced MRI scans more difficult.

General principles of chemotherapy administration in tumors of the CNS are similar to those of other tumors of the body. The CNS lacks a lymphatic system and, because of the presence of the BBB, extraneural metastases are uncommon. Thus the goal of treatment remains focused on the brain and spine. Some agents may not fully penetrate through the BBB,[285,286] depending on the characteristics of the drug and local breakdown of the BBB. Although the chemical structure of compounds should be an important consideration in their predicted ability to penetrate the BBB, and thus have the potential for clinical activity, many hydrophilic drugs have demonstrated activity in brain tumors. However some hydrophobic agents, which should easily traverse the BBB, do not traverse it. Even with extensive knowledge of the hydrophobicity of a drug, one cannot predict with certainty whether it will have activity in CNS tumors. The platinum drugs, for example, which would not be predicted to penetrate into the brain significantly, are active agents for various tumors in the brain and spine. This outcome may in part relate to the breakdown of the BBB around tumors, resulting in penetration of drugs into restricted areas. One important variable that can significantly affect BBB penetration is the degree of protein binding. To overcome this problem of drug delivery, direct application of drugs into surgical cavities or cysts is possible. Hydrostatic pressure gradients moving from tissue into an empty cavity draw most of the drugs away from the tumor and likely account for the limited activity of chemotherapeutic agent–impregnated wafers along the resection margin.

Intrathecal or Intra-Ommaya Chemotherapy

Intrathecal administration of chemotherapy can overcome the blood-CSF barrier and is of importance in tumors with a predilection to seeding of the brain and spine. This technique is not safe in patients with obstructed CSF flow, but for patients without this problem who also lack diversional shunts that would draw the drugs out of the CSF spaces, high concentrations can be delivered.[287] Because repeated access to the lumbar spine can be uncomfortable, insertion of an Ommaya or Rickham reservoir may reduce the difficulties of repeated administration. To assist in the delivery of chemotherapeutic agents into the CSF, insertion of reservoirs that sit on top of the skull or in the subcutaneous tissue of the abdomen or flank can make repeated administration more practical. Although a number of new agents have been investigated for intrathecal or intra-Ommaya/Rickham administration, including busulfan, etoposide, and mafosfamide,[288-291] overall a limited number of agents may be safely administered to this compartment, including standard intrathecal agents used in leukemia (e.g., methotrexate and cytarabine), etoposide,[292] topotecan,[293] and liposomal cytarabine.[294,295]

An important approach to increasing the penetration of chemotherapy into the brain has been the use of high-dose systemic therapy followed by stem cell rescue. The efficacy of this approach and management of the associated toxicities continue to be an area of significant study (discussed later).

Newer methods of targeting penetration of drugs into the CNS include BBB disruption agents. These agents are in clinical trial and are designed to temporarily open up the tight junctions protecting the CNS.[296] They are typically administered just before the active anticancer agent is administered. Although this approach is promising and deserving of additional evaluation, a common problem to date has been the opening of the BBB in normal areas of the brain, resulting in greater toxicities to uninvolved areas. In a similar approach new lipophilic carrier molecules have been designed to help transport drugs across the BBB, and further advances in these areas are expected.

Convection-Enhanced Delivery

With the movement of fluids away from areas of high interstitial pressure to areas of low interstitial pressure, passive diffusion of drugs deep into tumors is unlikely to occur in sufficient concentrations to be effective. To overcome this problem developments in convection-enhanced delivery have been reported. These techniques require the implantation of small catheters that can be tunneled under the scalp, which then penetrate the solid tumor parenchyma or adjacent brain. By injecting drugs under high pressure, these agents move through the interstitial space between cells, giving the drugs an opportunity to kill tumor cells, even in critical areas of the CNS such as the pons.[297] Because tumors usually penetrate along the pathway of least resistance, similar to fluids under pressure, this technique allows the drug to spread out in a fashion similar to that of the infiltrating tumor. A number of candidate molecules designed for convection-enhanced delivery are being developed. This technique should be equally well suited to small-molecule inhibitors, chemotherapeutic agents, biologic drugs (including large protein molecules), and gene vectors. Advances in drug packaging may permit control of drug delivery, improving the activity of this approach.[298]

Novel Chemotherapeutic and Biologic Agents

The revolution in the molecular classification of adult and pediatric tumors has significantly advanced our understanding of pathways implicated in tumor initiation, progression, and metastases. These pathways have also become important targets for new therapy approaches that are included in the realm of chemotherapy but differ in many fundamental ways. The unique mechanism of action of these inhibitors, and their lack of typical chemotherapy-related toxicity (e.g., myelosuppression) make them ideally suited for combination with traditional chemotherapy and radiation therapy.[5,299] In addition to classic cytotoxic agents, the use of agents that modulate the epigenome, such as histone deacetylases, which modify DNA methylation, a process critical in gene regulation, may allow apoptotic or differentiation genes to be reactivated while turning off proliferative pathways.[300,301]

The development of new formulations of old drugs also deserves comment. Many drugs that were tested in children with tumors of the CNS did not demonstrate activity, which may have been the result of poor penetration or unknown pharmacokinetics. Modifications to older agents such as doxorubicin by pegylation and liposomal encapsulation will require additional clinical testing.[302] Even vincristine, which is commonly used in pediatric patients with CNS tumors despite a lack of clear data demonstrating its activity in these diseases, is being redeveloped to improve its potential activity.[284,303]

Numerous targeted agents are now available, and each will require some early pediatric clinical experience regarding dosing and tolerability.[304] Unfortunately most biologic agents are unlikely to possess significant single-agent activity or resistance will develop, although some exciting responses have been observed in a number of different pathways, including SHH and BRAF.[305] Many of these drugs may be better at slowing tumor progression and will need to be used in combination with other molecular inhibitors, radiation therapy, and chemotherapy. These targets may also have important roles as prognostic markers, as well as therapeutic targets.[306,307]

Small-Molecule Inhibitors. The sequencing of the human genome and the identification of a number of critical signaling pathways, especially the receptor tyrosine kinases, have provided the basis for a whole new class of anticancer agents.[308] Normal cells transmit signals from the external environment to the nucleus via receptor tyrosine kinases. These molecules sit on the cell surface and homodimerize or heterodimerize in the presence of ligand, which results in a conformational change in the intracellular domain of the receptor. This process allows a phosphorylation event on the cytoplasmic component of the receptor that begins a complex cascade that results in the alteration of cell function. Many tumors use these receptors or their pathways to drive cell proliferation and migration, as well as decouple cell repair and apoptosis.[309]

The activation of receptor tyrosine kinases results from the phosphorylation of a tyrosine residue in the intracellular domain of the receptor. This process can be blocked by the steric interference of small molecules designed to fit into the phosphorylation pocket. By carefully designing the shape of these molecules, the ability to define the specificity of these drugs to related receptors means that some inhibitors can disrupt only a single receptor or entire families of receptors. A number of experimental studies of these inhibitors have been tested in children with brain tumors, including those targeting the platelet-derived growth factor receptor (PDGFR)[310] and ras pathways.[311] One problem with small-molecule inhibitors, as with other agents targeting the CNS, is the need to get drugs across the BBB; small molecules are ideally suited for this purpose, but efflux pumps are present that may expel the agents, resulting in limited activity.[312] Unfortunately this mechanism must be evaluated on a drug-by-drug basis.

Immunotherapy

Although the brain and spine are considered immunologically privileged sites, the presence of lymphocytic infiltrates in many brain tumors suggests that activation of the immune system is possible. Significant attempts to activate the immune system against these tumors,[313] especially malignant gliomas, have followed two main approaches. Some groups have attempted to increase the immune activation of lymphocytes by cytokine stimulation of the innate immune system. In the second approach a patient's own tumor is required to generate tumor-specific immune-activated cells.[314] While more is learned about how immune cells interact with and are activated by tumors, opportunities to develop immunotherapies may become more feasible,[315,316] and some early encouraging results are already being reported.[317,318]

Gene Therapy

The use of gene vectors for the treatment of brain tumor allows for the expression of a large array of different molecules.[319] Many experimental approaches have focused on modulators of the immune response.[320] An important component in the expansion of these approaches will be the identification of different vectors,[321] as well as improvement in direct delivery of large molecules directly into the brain to bypass the BBB.[322]

Antiangiogenic Agents

During the past few decades the role of angiogenesis in the development of cancer has evolved from a novel hypothesis to a fundamental area of research and therapeutic intervention. Although not brain tumor–specific, angiogenesis has been a hallmark of the progression of malignant gliomas. A large number of antiangiogenic inhibitors are now in clinical trials and have focused on targeting the cytokine vascular endothelial growth factor,[323,324]; other inhibitors of the angiogenic cascade are being tested as well.[325,326] Although bevacizumab has been extensively tested in adults with malignant gliomas, its role in pediatric tumors remains unclear.[327,328] A developing area ideally suited for pediatric patients has been the use of oral antiangiogenic chemotherapy.[329-331] The principle behind this approach is the use of very-low-dose chemotherapy that targets dividing endothelial cells rather than tumor cells. A number of low-dose chemotherapy approaches are being tested, and preliminary results are encouraging.[226,332-336]

Suppression of Tumor Resistance

The innate resistance of many tumors to cytotoxic agents, especially those of glial origin, is well documented by the near-complete and rapid progression of HGGs after upfront radiation and chemotherapy.[337] Tumors can use a number of pathways to avoid cell death when confronted with DNA-damaging agents. Temozolomide has become widely used in conjunction with radiation therapy in adults and has demonstrated clear activity in these patients. Although this combination has demonstrated prolongation in time to progression of the disease, in the vast majority of patients the disease will eventually progress as resistance mechanisms are activated. To help overcome this problem recent clinical trials have begun testing molecules that can bind and inactivate the enzymes responsible for resistance. One such example is O(6)-benzylguanine (O(6)-BG), a small molecular compound that can bind the enzyme O(6)-methylguanine-DNA methyltransferase (MGMT), which functions to remove the methyl group on the O(6) position of guanine after temozolomide treatment.[338] By treating the patient in advance with O(6)-BG, all free MGMT can be consumed, at which point administration of temozolomide can damage the DNA. Although still early in pediatric testing, this approach offers considerable opportunity.[339,340] Additional resistance pathways have been identified in pediatric and adult brain tumors that may guide therapeutic approaches, as well as the development of new inhibitors of the resistance pathways.[341,342] For example mutations within the *PMS2* mismatch repair gene, which can lead to tumorigenesis and treatment resistance, may be influenced by the addition of retinoic acid.[343]

High-Dose Chemotherapy with Stem Cell Rescue

The principles of high-dose chemotherapy and stem cell rescue are similar to those for other malignant diseases. Many brain tumors, especially those of primitive neuroectodermal origin, such as medulloblastoma and CNS PNETs, have demonstrated dose-dependent chemotherapy responses.[344-346] This technique has therefore been used extensively in children with relapsed disease after standard upfront therapy[347-349] and in young children and infants.[350-353] In light of the long-term neurocognitive effects of radiation therapy for young children, particularly for diseases that require craniospinal radiation therapy, high-dose chemotherapy with autologous stem cell rescue (ASCR) currently serves as the backbone treatment in many infant protocols around the world. Although the conditioning regimens, disease histologies, and patient characteristics have differed across multiple clinical trials and retrospective studies, this approach has demonstrated positive results in patients who could achieve minimal residual disease prior to transplant.[354-356] The addition of this modality with other therapies remains to be tested and may influence the utility of this approach in persons without minimal residual disease or the ability to maintain the disease-free state.[357] The role of high-dose chemotherapy with stem cell rescue is debatable, however, in the recurrent setting.[358] The evaluation of patients after transplantation can be complicated by the presence of therapy-related signal changes on MRI scan, including heterogeneously enhancing lesions, often causing clinical symptoms related to their location. Although these lesions can appear consistent with disease progression early after transplantation, they do not progress and need to have long-term follow-up with regard to their clinical significance.[359]

PEDIATRIC BRAIN TUMORS

Gliomas

Glial tumors are usually classified according to the type of glial cell that constitute the tumors—astrocytomas, ependymomas, and oligodendrogliomas. Each is further divided by morphologic features, degree of invasiveness, and location and is assigned a grade ranging from I to IV as the features of malignancy increase. In pediatrics, the grading of astrocytomas has been defined by the WHO or St. Anne-Mayo system and is predictive of patient survival.[213,360] In pediatrics, the modified WHO classification of CNS tumors[197] has become the standard classification system (see Table 57-3). Astrocytomas can be classified as low grade (WHO grades I and II) or high grade (WHO grades III and IV). LGGs may consist of relatively pure tumors such as a juvenile pilocytic (grade I) or fibrillary (grade II) astrocytoma or mixed populations of both glial and neuronal lineages, such as ganglioglioma or glioneurocytoma. The classification of several other subtypes is still being debated. Although the differentiation of HGG from LGG is universally used and based on degree of atypia, mitoses, necrosis, and vascular proliferation, with greater molecular definition of astrocytic tumors, the need to separate grade I from II and grade III from IV tumors regarding treatment and prognosis is increasing. Pediatric gliomas can also be discussed in the context of location, rather than grade. This approach recognizes some of the unique aspects of the environment in which tumors of similar histologies can grow and its effect on treatment and prognosis (Box 57-2).

Box 57-2 Histologic Classification of Low-Grade Gliomas

- Astrocytic tumors
  - Pilocytic astrocytoma
  - Pilomyxoid astrocytoma
  - Diffuse astrocytomas (fibrillary, protoplasmic, gemistocytic)
  - Pleomorphic xanthoastrocytoma
  - Subependymal giant cell astrocytoma
- Oligodendroglial and mixed glial tumors
  - Oligodendrocytoma
  - Oligodendroglioma
  - Oligoastrocytoma
- Mixed glial-neuronal tumors
  - Gangliocytoma
  - Ganglioglioma
- Dysembryoplastic infantile astrocytoma and dysembryoplastic infantile ganglioglioma
- Dysembryoplastic neuroepithelial tumor
- Special locations that are often not biopsied
  - Optic pathway gliomas
  - Tectal gliomas
- Cervicomedullary gliomas

Low-Grade Glioma

Supratentorial, Cerebellar Pilocytic, and Other Low-Grade Astrocytomas. LGGs represent the most frequent group of brain tumors that develop during childhood. According to the latest statistical report from the Central Brain Tumor Registry of the United States,[22] the annual incidence of pediatric LGGs in the United States is 2.1 per 100,000 persons. PAs, which make up the majority of LGGs, are well-circumscribed tumors classified as WHO grade I.[361] These tumors were formally referred to as juvenile PAs but are now classified simply as PAs. Grade I tumors are the most common LGGs found in children, representing 20% to 30% of all childhood brain tumors. PAs typically appear in the first two decades, with no clear gender predominance. They usually grow slowly, although their presentation can occur as acute deterioration as a result of obstructive hydrocephalus. NF-1 is the best example of a condition associated with an increased risk of PA in up to 15% of these patients.[362] The localization of PAs in the context of NF-1 and their improved long-term prognosis is well established,[363,364] although the molecular basis for this difference is unclear. Other predisposing factors such as common cytogenetic abnormalities are uncommon.[365] Low-grade astrocytomas typically lack epidermal growth factor receptor (EGFR) amplification,[366] although defects in the BRAF pathway have recently been reported and are present in the majority of cases.[367]

Clinical Presentation. Low-grade astrocytomas in children have a varied course, ranging from dissemination and persistent recurrence to spontaneous regression without therapy, and they behave differently from low-grade astrocytomas in adults.[368,369] The biologic factors that account for these differences remain investigational, although telomere length may play an important role.[370] PAs commonly occur throughout the brain, including the optic pathways, optic chiasm–hypothalamus, thalamus and basal ganglia, cerebral hemispheres, cerebellum, and brainstem (dorsally exophytic brainstem glioma). PAs of the spinal cord are less common.

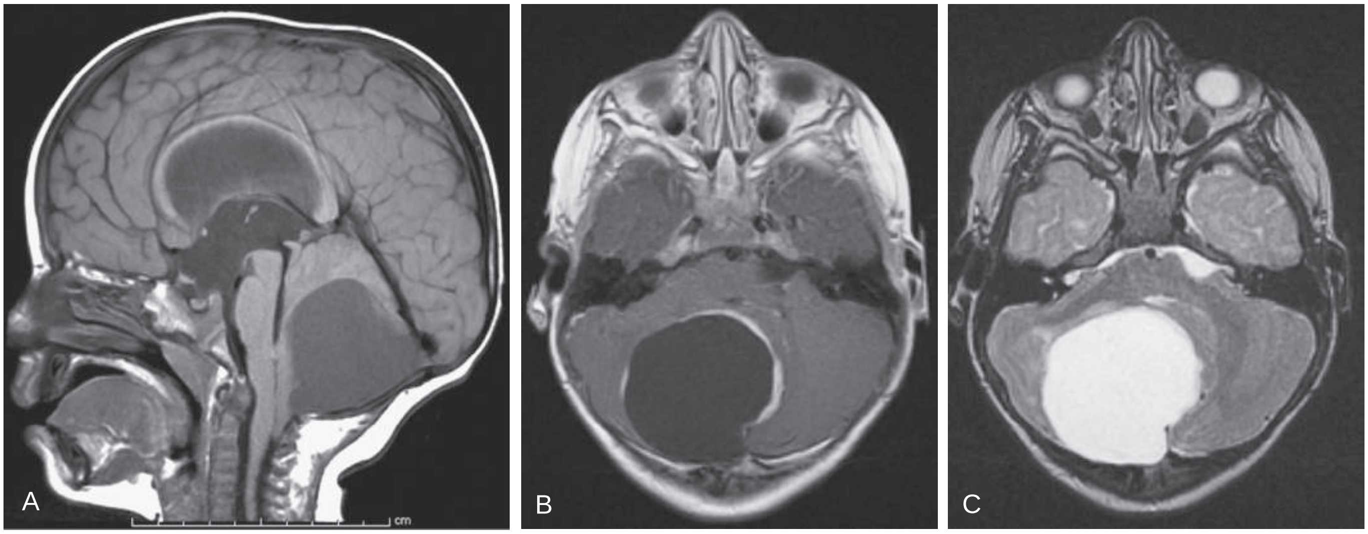

Figure 57-18 Posterior fossa pilocytic astrocytoma (juvenile pilocytic astrocytoma). **A,** A sagittal T1-weighted image without use of contrast material. **B,** An axial T1-weighted image with use of contrast material. **C,** An axial T2-weighted image.

The spectrum of clinical manifestations of a PA depends on the site of origin, its size, the age of the patient, and the presence of raised ICP. Cerebellar PAs and dorsally exophytic brainstem PAs usually present with symptoms of increased ICP, such as headache, nausea, and vomiting. Children may also present with a relatively long history of progressive focal neurologic deficits, including gait disturbance, and infants may present with progressive secondary macrocephaly. Signs of chronicity such as bone remodeling, scoliosis, or hemihypertrophy may be present, depending on the primary tumor location. The diencephalic syndrome is unique to low-grade astrocytomas, both PA and pilomyxoid astrocytoma, is typically seen in infants whose tumors arise from the hypothalamus or optic pathways, and consists of emaciation, emesis, euphoria, and normal linear growth.[371,372] Although many other deep-seated low-grade glial tumors cannot be resected, patients with diencephalic syndrome appear to have a worse prognosis, suggesting that subtle biologic differences among these tumors and other PAs may exist. Leptomeningeal dissemination is associated at diagnosis in 3% to 5% of cases.[373,374]

Imaging and Histology. The typical MRI appearance of a grade I astrocytoma is that of an intensely homogeneous, well-circumscribed, contrast-enhancing lesion with minimal surrounding edema. Lesions are typically bright on both T1- and T2-weighted images. Tumoral cysts are more prevalent in the cerebellum than in the cerebrum (Fig. 57-18) and often possess a contrast-enhancing mural nodule. Apparent diffusion coefficient imaging may be useful in differentiating PAs from higher grade astrocytomas.[375] Imaging characteristics can help with the differential diagnosis of low-grade lesions preoperatively but are not specific enough to be used without biopsy confirmation.[376]

Histologic examination reveals a biphasic pattern, with a compacted component containing bipolar cells (Fig. 57-19) and Rosenthal fibers and a loose cellular array containing microcysts and eosinophilic granular bodies. Rosenthal fibers and eosinophilic granular bodies are pathologic hallmarks of pilocytic astrocytomas, although they can be observed in other diseases of the CNS. Rosenthal fibers are brightly eosinophilic, hyaline masses composed of alpha-B-crystalline and are best seen on tumor smear preparations (Fig. 57-20). Eosinophilic granular bodies are globular aggregates within astrocytic processes and are also best visualized with smear preparations. PAs stain intensely with the GFAP immunoreagent. Invasion of the overlying meninges and adjacent brain parenchyma is commonly observed. Mitoses are rare, and the MIB1 labeling index is usually lower than 4%.[377] Although the pathologic criteria for anaplastic astrocytoma include the identification of mitoses, their presence in PAs does not indicate a higher grade.

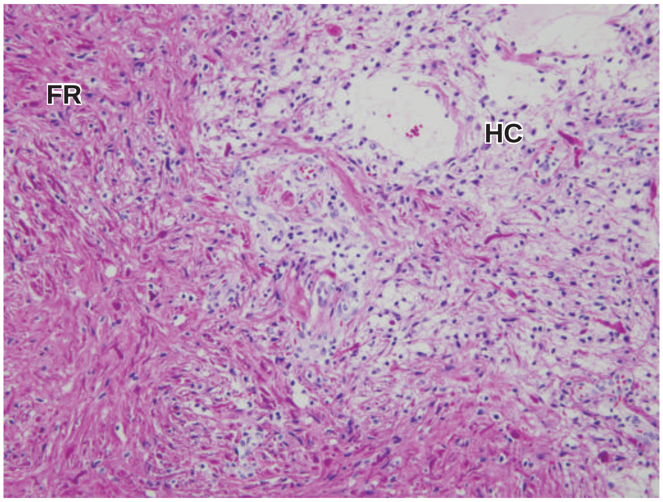

Figure 57-19 Pilocytic astrocytoma. Shown is a biphasic pattern of compact, fiber-rich *(FR)* tumor and hypocellular *(HC)* areas with microcysts (×200).

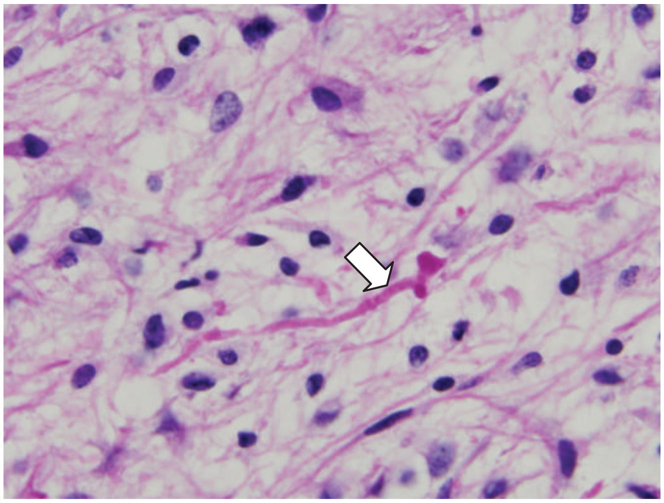

Figure 57-20 Rosenthal fiber *(arrow)* in a pilocytic astrocytoma (hematoxylin and eosin; ×1000).

Inexperienced pathologists can often misinterpret these mitoses, resulting in a diagnosis of a malignant rather than an LGG. Similarly PAs can have vascular proliferation, a hallmark of glioblastoma multiforme (grade IV astrocytoma), although, again similar to that of the presence of mitoses, this does not indicate transformation to a more malignant phenotype. Rarely PAs can present with diffuse leptomeningeal dissemination, especially in the variant of pilomyxoid astrocytoma.[378-381] Characteristic of the unique biology of PAs, each of the metastatic lesions continues to behave as a low-grade astrocytoma with a slow, indolent course. These tumors therefore are not difficult to treat as a result of their metastatic phenotype but rather as a result of their slow, persistent recurrences.

Molecular and Genetic Characteristics of Pediatric LGGs. Recent efforts in the characterization of genomic alterations in pediatric LGGs have significantly expanded our understanding of the biology of those tumors.[210] Genomic alterations of the *BRAF* gene, resulting in alteration of the MAPK pathway, are prominent in pediatric but not adult LGGs.[382] Other genomic alterations affecting PI3K/AKT, EGFR, PDGFRa, FGFR1, TrkB, MybL1 and VEGF signaling pathways have been described in a subset of pediatric LGGs.[383,384]

Importantly pediatric LGGs present distinct molecular alterations compared with adult LGGs. Tumor protein p53 *(TP53)* mutations are frequent in adult LGGs (up to 60% to 70%)[385] but are rare in pediatric LGGs.[386-388] Deletion of 1p and 19q is the most frequent copy number alteration in adult oligodendrogliomas.[389,390] In contrast very few 1p-19q codeletions have been reported in pediatric LGGs.[391,392] IDH1 and IDH2 mutations occur in about 70% of adult LGG,[393] whereas these mutations are very rarely described in the pediatric population.[394,395]

BRAF Truncation-Duplication. The high incidence of LGGs in patients with NF-1 prompted initial investigation into the role of the MAPK pathway in pediatric LGG tumorigenesis.[396] Early comparative genomic hybridization studies performed on pediatric LGGs, especially PAs, identified a significant recurrent gain of the 7q34 region containing the BRAF locus. This region is amplified in 50% to 90% of pediatric PAs, with the highest frequency in tumors of the posterior fossa and of the hypothalamic/chiasmatic region and less frequently in fibrillary astrocytomas and oligodendroglial tumors,[397-399] and they are thought to have a better prognosis than other LGGs.[400] Further genomic studies found that the 7q34 gain corresponded to a *BRAF* duplication and *KIAA1549* insertion.[401,402] In vitro validation showed that this gene product is constitutively active, leading to downstream upregulation of effectors of the MAPK pathway, MEK and ERK.[403] One short form of the *KIAA1549-BRAF* fusion induces anchorage independent growth in vitro.[404,405] Also short-term cultured pediatric LGG lines showed significant diminution of cell proliferation rate using pharmacologic inhibitors of MEK1 and MEK2.[401] Other partners of BRAF fusion have recently been identified that involve either SRGAP3 or FAM131B, all causing MAPK pathway activation.[404-408] Although break points between *BRAF* genes differ in those variants, they all result in the loss of the N-terminal inhibitory domain of *BRAF*, leading to the constitutive activation of the BRAF kinase. Recent functional studies using BRAF fusion variants have highlighted the importance of the context in which this genomic alteration drives tumor growth. Kaul et al and colleagues[409] demonstrated that in vivo transfection of the BRAF fusion transcript in mature astrocytes was not able to induce glioma tumors, whereas transfected neural stem cells were able to develop tumors. Another recent study comparing the overexpression of the BRAF-KIAA transcript in neural stem cells of different regions within the brain showed that tumors appeared only in neural stem cells located in the third ventricular region.[73]

BRAF V600E Point Mutation. BRAF V600E mutation has been described in a variety of cancer subtypes including melanoma, colorectal cancers, papillary thyroid carcinoma, non–small-cell lung carcinoma, and leukemia. This mutation enhances BRAF kinase activity and leads to the constitutive activation of the MAPK pathway. In contrast to BRAF truncation-duplication, which is strongly associated with grade I histology, the BRAF V600E mutation occurs more frequently in grade II pediatric LGGs (PLGGs), especially fibrillary astrocytomas, gangliogliomas, pilomyxoid astrocytomas, and pleomorphic xanthoastrocytomas (PXAs).[388,410-413] V600E mutation was also described as transforming fibroblasts in vitro,[405] suggesting that this specific genomic alteration drives cell proliferation in a subset of PLGGs. Interestingly a recent study showed that BRAF V600E mutation promotes neural stem cell transformation followed by senescence, which may parallel the natural history of PLGGs.[414]

Other Genomic Alterations Affecting Key Pathways. In addition to the MAPK pathway, other pathways such as PI3K/AKT/mTOR, EGFR, SHH, and VEGF have been described to be altered in PLGGs. Although PTEN deletions and p16 deletions were previously identified in anaplastic astrocytomas and therefore associated with a more aggressive phenotype of astrocytic tumors,[415] a recent study of 32 PLGGs showed that 44% had PI3K/Akt/PTEN/mTOR activation, mostly through PTEN promoter methylation.[416] Additionally BRAF fusion transcript transfection in vivo is associated with mTOR pathway activation through the S6-kinase cascade.[409] EGFR amplification, assessed by genomic hybridization and fluorescence in situ hybridization, was described in a subset of disseminated PLGGs, suggesting that the EGFR pathway may play a role in a fraction of invasive LGGs.[374] Evidence of WNT pathway activation in a subset of PAs, especially in young children, has been highlighted by a recent study showing that the patched *(PTCH1)* gene, coding for the PTCH receptor, was highly expressed in a subset of PAs, especially in patients younger than 10 years.[417] PAs might also carry abnormal function of the VEGF pathway, supported by the observation that vessel architecture of those tumors is often immature and unstable, comparable with that of HGGs.[418] The active phosphorylated forms of the VEGF receptors 1, 2, and 3 have been shown to be highly expressed in tumor vasculature in PAs.[419]

Recently genomic alterations of the transcriptional activator MYB, a known oncogene in other tumor subtypes, especially T-cell acute lymphoblastic leukemia,[420] have been identified in PLGGs. MYB amplification and focal deletions have been described in fibrillary astrocytomas and in angiocentric gliomas, respectively.[384,421]

Management. Surgery is the mainstay of therapy for most pilocytic and other low-grade astrocytomas.[422] GTR is often curative, even though residual microscopic disease may often be left behind.[423,424] Radiation therapy and chemotherapy are typically not required as part of upfront therapy after a complete resection.[425] Surgery is also an effective method of seizure control in patients with LGGs, especially those of the temporal lobes.[426,427] PLGGs in more eloquent areas may not be amenable to surgical resection. Because the OS even of nonresectable PLGG is very high, surgical resection should not be attempted when a significant risk of morbidity exists.[428] Unfortunately even in patients with complete resection, the presence of a tumor and surgical intervention can be associated with some long-term adverse effects.[429] PAs of the optic pathway in patients with NF-1 do not require surgical confirmation unless atypical radiographic or clinical features are present.[430] Patients with tectal gliomas require CSF diversion but do not benefit from biopsy; they can be diagnosed on the basis of the presence of hydrocephalus and MRI appearance of the lesion alone. In the largest prospective series of patients with PLGG stratified to observation, chemotherapy, or radiation therapy, the overall outcome of these patients was similar to that of patients reported in other independent series and is an important milestone in the assessment of more than 1000 patients with PLGG.[431]

Progressive or unresectable PAs, or those arising in infants or children that cause alterations of vision or other neurologically relevant symptoms, may require adjuvant treatment.[432] Chemotherapy is assuming an increasingly important role in the management of unresectable and/or progressive LGGs, diencephalic LGGs in younger patients, and other unresectable tumors (Table 57-5). Various combination regimens, such as carboplatin and vincristine or thioguanine, procarbazine, lomustine (CCNU), and vincristine (TPCV) have produced consistent, durable responses,[433-435] reviewed by Perilongo.[436] Monthly carboplatin is more easily administered but may have less activity[437-439] and requires additional study.

With multiagent combinations, stabilization of tumor occurs in almost 50% of patients, and radiographic response is observed in an additional 40%. Median time to progression is approximately 3 years, and up to 60% of patients will eventually demonstrate tumor growth. The Children's Oncology Group (COG) recently completed a prospective randomized phase III clinical trial examining outcomes of children younger than 10 years treated with vincristine and carboplatin versus TPCV. The TPCV arm showed a trend toward a superior 5-year event-free survival (EFS) compared with the vincristine and carboplatin arm (52% vs. 39%, respectively), although no statistically significant difference was found.[440] The ability to retreat these patients with multiple regimens has allowed most patients to avoid radiation therapy, especially early in life when the long-term morbidity of this modality is greatest. Although the time to progression may appear short and the overall progression rate of 50% to 60% appears high, these chemotherapy regimens are well tolerated, with few long-term complications. This outcome is in contrast to radiation therapy, which demonstrates a significantly improved response rate (85% response or stable disease) and duration of disease control (longer than 10 years)[441]; however, radiotherapy also entails significant long-term morbidities, such as neurocognitive, vascular, hormonal, and second tumor risks. Because most children with LGGs will be long-term survivors, this is exactly the population that would benefit from the avoidance of the late effects of radiation therapy.[442] To reduce the volume of normal tissue, stereotactic conformational external radiotherapy,[443] stereotactic radiosurgical techniques,[444] and proton radiotherapy[445] have been evaluated in the treatment of recurrent and progressive PLGG tumors. However more focused delivery of radiation in patients with PLGGs only marginally mitigates the long-term sequelae, which include malignant transformation and second malignancy, vascular injury, and, depending on location, neurocognitive decline, endocrinopathies, and other neurologic deficits. These significant and largely irreversible iatrogenic sequelae, conferred in the treatment of a disease whose natural history is self-limiting in most cases, provide an argument in favor of a radiation-avoidance strategy for children with PLGG.

The overall improved outcome for patients with NF-1 has also been confirmed,[440] indicating that these tumors may have a unique biologic phenotype. Temozolomide (TMZ), an orally active alkylating agent with a favorable adverse effect profile, has been shown to have some activity as monotherapy for adult LGGs.[446] Although it has not been widely studied, it appears to have a low response rate in LGGs in children, with a median time to

Modified from Perilongo G: Considerations on the role of chemotherapy and modern radiotherapy in the treatment of childhood low-grade glioma. J Neurooncol *75:301–307, 2005.*

CR, Complete remission; *EFS,* event-free survival; *MR,* minor response; *ND,* newly diagnosed; *NF-1,* neurofibromatosis type 1; *OS,* overall survival; *PD,* progressive disease; *PFS,* progression-free survival; *PR,* partial remission; *SD,* stable disease; *TTP,* time to progression.

progression of 6.7 months, although many patients appear to have prolonged stable disease.[447,448] Responses with TMZ in disseminated low-grade astrocytomas have also been reported,[378] although another alkylator, cyclophosphamide, when given every 3 weeks, lacked significant activity.[449] The role of TMZ in combination with vincristine and carboplatin for PLGGs is currently being investigated. Other investigators have successfully used novel combinations containing 5-fluorouracil.[450] The metronomic application of vinblastine, a mitotic inhibitor, has resulted in some clinical responses or stable disease in children with LGGs who are unable to tolerate carboplatin.[332] Vinblastine is also being evaluated alone[451] and in combination with carboplatin in newly diagnosed patients. Although more information on the activity of these approaches is needed, responses in refractory LGGs have been reported with other metronomic-based chemotherapy approaches,[326] suggesting that angiogenesis may be an important pathway in these tumors. Antiangiogenic approaches, such as bevacizumab, have also been tested with some responses,[452-455] which is also consistent with the presence of vascular proliferation observed in these tumors. Chemotherapy may also allow for improved surgical resection of previously unresectable lesions and therefore should be continuously reevaluated as a therapeutic option.[456] Tumors treated with chemotherapy, even if they are not smaller, can be easier to resect because of less bleeding and a firmer texture at the time of the procedure. The recent identification of BRAF mutations in the majority of PLGGs offers the potential for targeted approaches to these patients. Phase II studies of the downstream inhibitor of mTOR, called everolimus, have recently been completed in this patient population with encouraging activity. In addition BRAF V600E small-molecule inhibitors are also being evaluated for patients with this specific mutation. Importantly the majority of patients with LGGs have the truncated fusion of BRAF (often referred to as the KIAA1549 fusion because this is the most common translocation). Treatment with a BRAF drug such as sorafenib or other V600E targeted agents would be expected to stimulate tumor growth as a result of a complex feedback loop, not to inhibit tumor growth.[457,458] Patients with truncated fusions will require therapy that accounts for this biologic pathway, and MEK inhibitors are just entering clinical trials for this patient population.

Although most chemotherapy regimens for LGGs have been reserved for children younger than 10 years, older children seem to derive equal benefit with the use of these regimens, potentially avoiding radiation therapy and the risks of second tumors, vasculopathy, and hormonal dysfunction.[459] The use of dose-intensive chemotherapy has been pilot tested in a small series of children, with results similar to those observed using standard doses.[460]

Radiotherapy is considered to be contraindicated in children with NF-1 and is usually deferred in children with PAs and other LGGs, especially in diencephalic and optic pathway tumors. Even highly focused radiation therapy in these locations cannot avoid the potential cognitive, endocrine, or vascular risks associated with radiation therapy. In spite of this highly focused radiation therapy is effective for LGGs and is without significant marginal failures, suggesting that these lesions have not deeply penetrated into surrounding brain.[461] Long-term concerns about second tumors, hormone dysfunction, and cognitive impact, however, still make this approach questionable for children.[462,463] Additional late effects of radiation therapy when used in younger children with diencephalic gliomas may include strokes related to a moyamoya-like syndrome.[85,464,465]

Prognosis. The prognosis for surgically resectable tumors is excellent after GTR. For patients with PAs whose tumors can be completely surgically resected, depending on location, the 10-year PFS approaches 90%.[380,466,467] Even in patients with incompletely resected lesions, treatment is not always required and, depending on the patient and clinical scenario, observation can be considered unless tumor or symptom progression is documented.[468] The most critical variable in the treatment of PAs is the anatomic location of the tumor. Complete resections are most difficult for tumors located in the brainstem, spinal cord, optic pathways, thalamus, and hypothalamus. As such, the PFS of children with centrally located tumors (e.g., in the optic chiasm, thalamus, or hypothalamus) is less than 50%.[467] Given the favorable toxicity profile of chemotherapy versus radiation therapy in young children, chemotherapy is preferred as the first therapeutic modality in young patients with tumors not amenable to gross total resection.[433] The use of chemotherapy as initial treatment in patients with centrally located or unresectable lesions allows for the delay of radiation therapy until the child is less likely to incur the serious developmental and neuropsychological sequelae of radiation therapy. Patients demonstrating radiographic response to chemotherapy have PFS similar to those whose tumors remained stable.[434,469] Ultimately the quality of survival depends on multiple factors, including the tumor location, the extent to which the tumor can be resected, timing of any radiotherapy, and adverse effects of surgery, chemotherapy, and radiotherapy.[470] Transformation of PAs into higher grade malignant gliomas is highly unusual.[471]

Optic Pathway Gliomas

Optic pathway gliomas (OPGs) represent approximately 4% to 6% of all primary pediatric brain tumors; the incidence is higher when asymptomatic lesions in patients with NF-1 are also included.[472] OPGs are evenly distributed between boys and girls. These tumors may involve various parts of the optic pathway, such as the optic nerves, chiasm, optic tract, and optic radiations. They may also infiltrate the adjacent hypothalamus and temporal lobes. Optic nerve gliomas are strongly associated with NF-1, although sporadic lesions are not uncommon. OPGs in patients with NF-1 have a more indolent course than those arising in patients without NF-1[473] and likely represent a different biology than sporadic tumors.[75,474] Although OPGs may be considered a subset of PAs, their unique features and management necessitate a separate discussion.[475,476]

Clinical Presentation. Most OPGs consist of PAs (WHO grade I).[477] The clinical course of OPGs can vary considerably, from an indolent mass in a child with NF-1 to a relatively aggressive, invasive, and expansile diencephalic tumor. Unilateral optic nerve gliomas often present with the classic triad of visual loss, proptosis, and optic atrophy. Optic nerve tortuosity, which can be present alone or in the context of OPGs in children with NF-1, does not necessarily define the presence of disease or the need for therapy.[478] Chiasmatic involvement may lead to unilateral or bilateral visual loss, a bitemporal visual field defect, and obstructive hydrocephalus as the tumor grows dorsally to obstruct CSF flow in the third ventricle. Further invasion into brain parenchyma may result in more pronounced visual field deficits, as well as hemiparesis. Chiasmatic tumors in infants present as large suprasellar masses that may also extend into the hypothalamus and third ventricle, producing hydrocephalus and endocrine abnormalities. In cases of hypothalamic extension, in addition to nystagmus, visual loss, and hydrocephalus, the diencephalic syndrome may occasionally be seen. This syndrome consists of hyperkinesia, euphoria, and emaciation, with preserved normal linear growth.[372] Failure to thrive is a common presentation of this syndrome, but in the context of a number of other conditions that may also cause failure to thrive during infancy, a delay in diagnosis of a brain tumor is not uncommon.[371] Endocrine deficiencies commonly accompany PAs in this location, and these tumors are more likely to have CSF dissemination in association with diencephalic syndrome, in spite of their histopathologic classification as benign.[479] Many patients with NF-1 will have long-standing, subtle ophthalmologic abnormalities, and thus regular visual evaluation is required. For these patients routine surveillance MRI scans are not indicated because many asymptomatic and clinically irrelevant tumors will be diagnosed, creating a treatment dilemma.[480]

Imaging and Histology. The clinical diagnosis of an OPG is suspected when a child presents with visual impairment, nystagmus, and/or optic atrophy. MRI of the brain or orbits typically shows a solid, cystic, or mixed type of tumor, with strong gadolinium enhancement. The imaging characteristics of LGGs of the optic pathway are similar to those of low-grade astrocytomas in other locations. The typical MRI appearance of a grade I astrocytoma is an intensely homogeneous, well-circumscribed, enhancing lesion with minimal surrounding edema (Fig. 57-21). Lesions are typically bright on both T1- and T2-weighted images. A higher ADC may predict a greater chance of progression.[481] MRI studies and clinical presentation may distinguish an OPG from other childhood tumors that arise in the suprasellar location, such as a GCT or craniopharyngioma. Histologically OPGs are usually grade I PAs or, less frequently, grade II fibrillary astrocytomas. Mixed LGGs have been reported in this region, but the overall therapeutic approach is not altered, because most of these lesions are not resectable at diagnosis. Tumors with an elevated MIB1 labeling index of more than 1% and p53 expression were more likely to be WHO grade II and had a worse outcome compared with tumors with an MIB1 and p53 labeling index less than 1%, all of which were PAs. PAs with a more aggressive behavior had an MIB1 labeling index of 2% to 3% but retained a low p53 labeling index of less than 1%.[477] Like LGGs in other locations, patients with sporadic OPGs have both BRAF V600E and truncated fusion KIAA1549 abnormalities.[399,482,483] BRAF abnormalities are rare in patients with NF-1 because of the existence of constitutive activation of the ras/raf/mek/MAPK pathway.

Management. The unpredictable clinical course of patients with optic pathway tumors has led to controversy

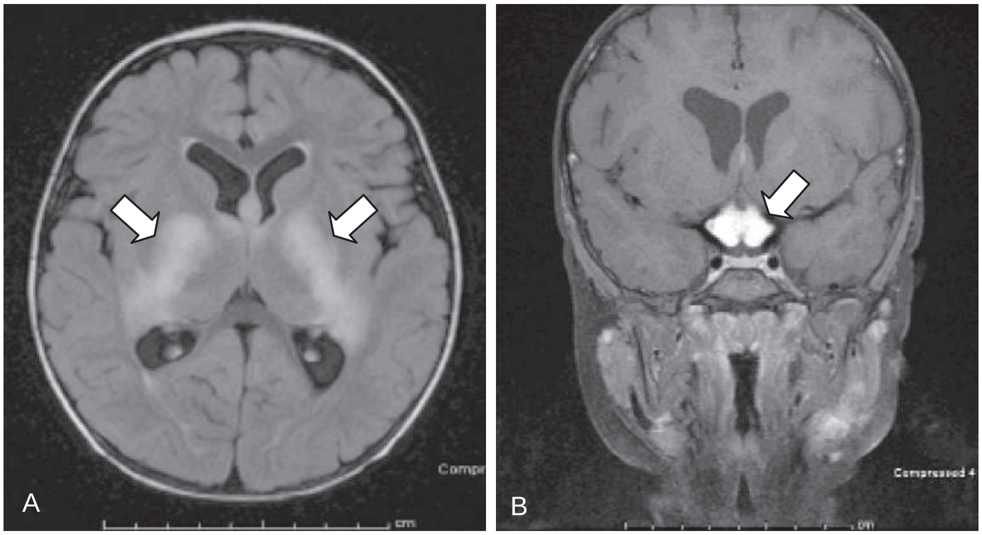

Figure 57-21 A large optic pathway glioma in a 2-year-old boy who does not have neurofibromatosis type 1. **A,** An axial T2-weighted fluid-attenuated inversion recovery image that demonstrates bilateral involvement of the optic tracts posterior to the chiasm *(arrows)*. **B,** A T1-weighted gadolinium-enhanced coronal image demonstrating the enhancing tumor expanding the optic chiasm *(arrow)*. The patient has no functional vision and is legally blind.

regarding the optimal management of these tumors. The clinical course, age of onset, severity of symptoms, size and extent of the tumor, and presence of NF-1 may all affect management decisions. Treatment is frequently started promptly in younger patients, in patients with progressive symptoms, and in those with more extensive CNS involvement, with the paramount concern being preservation of vision. Although progression can be easily quantified on an MRI scan, correlation between MRI findings and visual outcome is poor.[484] The initial treatment of choice is chemotherapy (see Table 57-5),[436] which may cause stabilization or regression[485] even in older children and adolescents[486] and is not associated with the neurocognitive decline observed with radiation therapy.[487] Surgery can be used upfront in selected cases, but the tumor may not be removed from the optic nerve without sacrificing vision.[488] Combination therapy with carboplatin and vincristine[433,489,490] or with TPCV[491] has been considered to have comparable beneficial effects. TPCV should not be used in children with NF-1 because of the increased risks of secondary tumors associated with alkylator-based treatment. When progression of the tumor occurs after treatment with vincristine and carboplatin, vincristine and actinomycin can be considered for patients with NF-1 to avoid further risks of alkylator therapy.[492,493] As for other LGGs, a number of new chemotherapy regimens are being developed (see Table 57-5) and can include bevacizumab and irintoecan,[452] vinblastine,[451] metronomic therapy,[335] and low-dose cisplatin and etoposide.[494] Current clinical trials targeting the mTOR pathway are under way, as is a phase II trial of lenalidomide.[495] Although delaying radiation therapy is paramount in young children, older patients may also benefit from these chemotherapy approaches and from delaying or avoiding radiation therapy.[459]

A randomized phase III COG study comparing the two regimens, carboplatin and vincristine versus TPCV for the treatment of progressive low-grade astrocytoma in children younger than 10 years, closed to accrual in 2005.[440] The results have shown that both regimens are well tolerated and can delay or obviate the need for radiation therapy in most patients, and that some patients will show improvement in vision with therapy.[496,497] Newer chemotherapy clinical trials for OPGs combine a number of agents such as TMZ with vincristine and carboplatin, and vinblastine and carboplatin. Although a definitive role for radiotherapy exists for the management of OPG,[498,499] current trends in treatment favor a delay in the initiation of radiotherapy in young patients.[500] Newer surgical techniques with direct administration of radiotherapy are also being explored and have demonstrated usefulness for selected patients.[501] Unlike LGGs in other areas, optic pathway tumors affect vision directly, and changes in visual fields and acuity can be a better determinant of both disease response or progression than are changes on MRI. Recent consensus criteria for the assessment of visual function in patients with NF-1 have been reported, and these criteria should provide a useful platform for the assessment of therapies that target OPGs.[502]

Prognosis. Although optic pathway tumors are almost always of low-grade histology, their location often results in serious morbidity. In patients with significant visual deterioration, progressive vision loss can continue for many years after the tumor has become stable on routine surveillance imaging.[503] The growth rate of these tumors, however, often slows during late childhood so that by adulthood, tumors may become quiescent and do not require further therapy.[442] Children with NF-1 have been shown to have a better PFS, although an age of younger than 1 year is clearly associated with a higher risk of tumor progression.[504] Patients with NF-1 appear to be at high risk for the development of moyamoya disease,[84] as well as radiation-induced second malignancies.[505] Patients with NF-1–associated optic nerve gliomas may remain stable for several years. Close observation and symptomatic management are recommended for these patients.

Low-Grade Astrocytomas of the Brainstem

Although most brainstem tumors are DIPGs, approximately 20% of brainstem tumors are low-grade astrocytomas involving the medulla, midbrain, tectum, or cervicomedullary, pontomedullary, or midbrain-pontine junction. Although 20% of nonpontine tumors in these locations can be classified as grade III or IV malignant gliomas, 80% are low-grade glial lesions with a much better prognosis.[506] These lesions differ from diffuse pontine gliomas by their clinical presentation and their imaging characteristics. Early identification of the type of brainstem lesion is critical in the workup, especially for consideration of neurosurgical intervention.[507]

Presentation. Patients with brainstem lesions can present with various clinical symptoms, depending on the location of the tumor. Medullary tumors are more common than midbrain tumors, and the male to female ratio is approximately 1 : 1.[508] In spite of the eloquent function of the brainstem, most patients with low-grade astrocytomas in this location have an indolent course with subtle neurologic findings. Most commonly patients present with cranial nerve dysfunction or head tilt. Lower motor weakness with subtle hemiparesis is also seen. Most parents have difficulty defining the start of the symptoms and refer to their child as having always been clumsy or weak. Rarely these tumors can be multifocal in nature.[509]

Histology and Imaging. Most low-grade brainstem tumors are either grade I or II astrocytomas; fewer than 20% are malignant astrocytomas. Imaging characteristics are similar to those of other LGGs; PAs (grade I) tend to be bright on T1- and T2-weighted images and enhance after administration of contrast material. Edema tends to be minimal. Fibrillary astrocytomas (grade II), by comparison, enhance to a lesser degree after administration of contrast material. The considerable overlap and variability in the imaging characteristics of grade I versus grade II astrocytomas, however, prevents accurate diagnosis based on MRI characteristics alone. The histologic features of brainstem low-grade astrocytomas are identical to grades I and II astrocytomas in other locations.

Management. Brainstem low-grade astrocytomas that remain focal can often be surgically resectable if they possess a plane between the brainstem and tumor.[510] If the tumor is completely resected, these patients are unlikely to need additional therapy. Given the good long-term outcome of this patient population, aggressive surgery should not risk damage in areas with poor tumor boundaries.[511] Incompletely resected brainstem low-grade astrocytomas have a high recurrence rate, and most of these patients will need additional therapy,[512] usually chemotherapy rather than radiation therapy, given the good long-term prognosis of these patients (see Table 57-5).[436] White matter tracts are often displaced by these tumors, and preoperative DTI can assist the neurosurgeon regarding the optimal approach to maximize resection while minimizing morbidity in this patient population.[513] Although postsurgical morbidity such as problems with swallowing can be significant, many patients eventually recover function, although this process can take many months and requires extensive physical and occupational therapy.[514] The chemotherapy options for these tumors are identical to those for low-grade astrocytomas in other locations and include vincristine and carboplatin or TPCV chemotherapy. Recurrence and need for retreatment are common, but most tumors will eventually stop growing while these patients enter adulthood.

Prognosis. Because most patients with a low-grade brainstem glioma will be long-term survivors,[510] it is important that the workup and treatment of these patients be adapted with this likely outcome in mind. Differentiation from DIPGs is usually easily made on the basis of imaging and clinical criteria. Surgical intervention must be based on the expectation that minimal long-term morbidity will result, given the large number of other treatment options available for these patients.

Low-Grade Thalamic Astrocytomas

Thalamic tumors are rare in pediatric patients, accounting for fewer than 5% of intracranial tumors. Most thalamic tumors are unilateral, and approximately 50% are low-grade astrocytomas.[515,516] Thalamic tumors occur at a slightly older age than do many other LGGs of childhood. Low-grade thalamic tumors present as unilateral or bithalamic in location, which appears to have prognostic significance.

Clinical Presentation. Thalamic tumors can present with a number of different clinical findings.[517] Raised ICP, tremors, motor deficits, seizures, and mood changes are the most commonly observed presenting symptoms.[518] Unlike in adult tumors, dementia is a rare presenting symptom.[519]

Imaging and Histology. Imaging characteristics of thalamic tumors are similar to those of gliomas in other locations (Fig. 57-22). Low-grade and high-grade histologies are approximately equally distributed, although pathologic classification of these tumors can be influenced by sampling error from small biopsy specimens.[520] The use of PET or SPECT imaging can help identify areas to be biopsied.[521] Although astrocytic histologies predominate, oligodendroglial tumors have also been identified.[516]

Management. The presence of tumor in the thalamus presents a number of management difficulties. Because of their location, complete resection is difficult,[519] although surgery can result in symptom improvement in selected cases.[522] Even attempts at biopsy can result in significant morbidity. The small amount of surgical material often raises concerns of sampling error in attempting to determine the histopathologic grade of the tumor. Biopsy of the most malignant component of these deep-seated

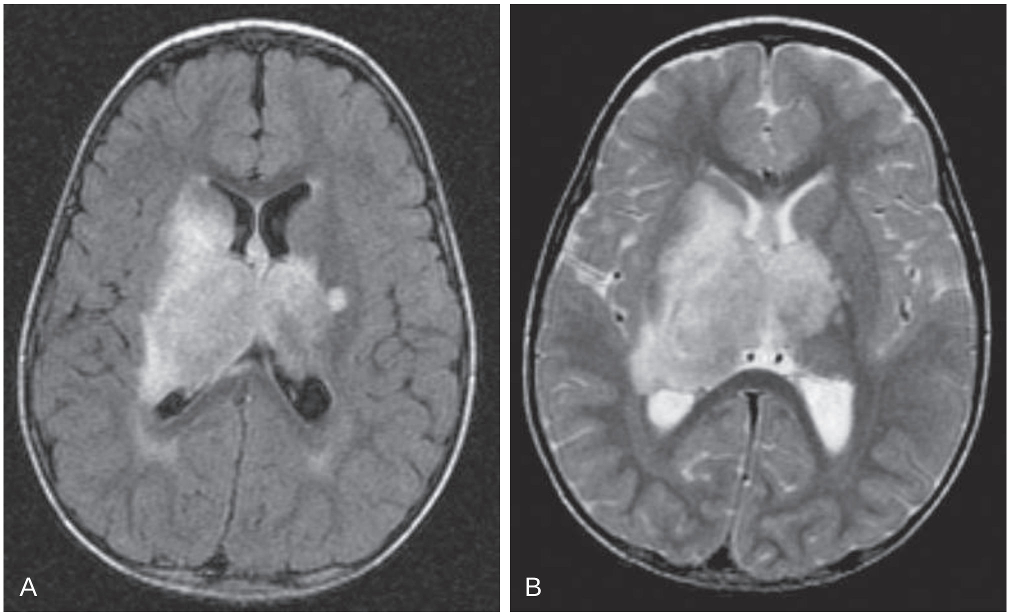

Figure 57-22 Bithalamic astrocytoma. **A,** An axial fluid-attenuated inversion recovery image. **B,** An axial T2-weighted image.

lesions can be guided with PET imaging.[521] This guidance is particularly important for astrocytic tumors, for which samples of sufficient size and content are needed to define the elements of tumor grade. In the analysis of children with thalamic lesions, most tumors are unilateral in nature, and approximately 50% to 60% are low-grade astrocytomas; the remaining 40% are high-grade lesions.[515] Some tumors are amenable to significant resection.[523,524] The response of low-grade thalamic tumors to chemotherapy and radiation is not known to be different from that of similar tumors in other locations. Thus younger patients are often treated initially with chemotherapy used for other low-grade astrocytomas (Table 57-5).[436] In those with rapid progression or histologic verification of high-grade features, radiotherapy can be used, although a significant portion of the brain will receive a substantial dose, resulting in long-term toxicity for survivors.

Prognosis. Contrary to some reports of very poor outcome for bithalamic astrocytomas of any grade,[525] five of nine patients were long-term survivors in one retrospective series.[515] Part of the difficulty in assigning an accurate prognosis to these tumors is the limited biopsy material available for assessment. With a number of reports of survivors now available, even in the context of bilateral disease, all young patients should be given a trial of chemotherapy.

Low-Grade Diencephalic Astrocytomas (Diencephalic Syndrome)

Diencephalic tumors remain a unique and poorly understood subtype of PLGGs. They typically occur in young infants, although a few patients have presented late in the first or second decade of life.[526] A high incidence of dissemination throughout the neural axis has been recognized[509] and may relate to the increased frequency of the pilomyxoid variant in this location. The presence of failure to thrive in infants often leads to an extensive and prolonged workup for gastrointestinal abnormalities before the correct cause is identified.[527] The presence of diencephalic tumors with early age of onset and the propensity to disseminate suggest that unique biologic differences may exist among these tumors and other low-grade astrocytomas, although no specific abnormalities have yet been documented.

Clinical Presentation. Diencephalic low-grade astrocytomas are differentiated from other LGGs in children by their presence around the hypothalamus–optic chiasm and a unique constellation of symptoms, including the three “E’s”—emaciation, emesis, and euphoria. In spite of severe failure to thrive that is often seen, most infants retain normal growth rates and maintain normal pituitary secretion prior to surgical resection.[526] Although an accurate clinical picture for these patients continues to be defined, because many lack the typical constellation,[372] their management is difficult because of the deep-seated nature of these lesions and the frequent presence of leptomeningeal dissemination at diagnosis.[528] As such, these patients require full craniospinal imaging at diagnosis, along with CSF analysis. Any patient presenting with symptoms of spinal disease needs to undergo immediate restaging.

Imaging and Histology. The imaging characteristics of diencephalic LGGs do not differ from those of low-grade astrocytomas in other locations. Lesions are centered around the hypothalamus and chiasm, are bright on T2-weighted images, and usually show homogeneous enhancement after administration of contrast material.[529] The lesions are typically PAs or fibrillary astrocytomas, although the pilomyxoid variant can also be observed in this location.[520] These tumors cannot be differentiated by mutational status of BRAF because some patients have the BRAF V600E mutation, some have the BRAF truncated fusion KIAA1549, and other patients have neither.[413]

Management. The approach to therapy follows that used for other low-grade astrocytomas. Because of the young patient age and deep location of these tumors, radiation therapy is usually contraindicated and will result in significant cognitive impairment over the long term.[464] Most patients undergo maximal safe surgery, followed by chemotherapy with vincristine and carboplatin or TPCV (see Table 57-5).[436] Radiographic response or stable disease accompanied by weight gain is common.[371,530,531] High-dose chemotherapy has also been used successfully[532] as an investigational approach. Radiographic responses and improvement is weight have also been reported with bevacizumab and irinotecan.[452]

Prognosis. In spite of the low-grade nature of diencephalic tumors, patients with these tumors do less well than do patients with similar tumors located in the optic pathway, brainstem, or cerebellum.[431] In addition to the continued progression of these tumors, which leads to compression of vital structures, patients are at high risk for surgery-induced hypothalamic damage resulting in obesity.

Fibrillary Astrocytomas

Fibrillary (WHO grade II) astrocytomas are low-grade astrocytomas that are distinct from PAs. Precise determination of the incidence of fibrillary astrocytomas is difficult because many tumors, particularly those in deep structures of the diencephalon or brainstem, cannot be resected sufficiently to provide the material required to classify the tumor accurately. Thus the terms “fibrillary astrocytoma” and “low-grade astrocytoma” are often used interchangeably. Although all fibrillary astrocytomas are LGGs, most LGGs are PAs. Many tumors are classified as grade II astrocytoma with piloid features because a biopsy specimen may have been too small to identify all the elements required for classification as a grade I PA. Similarly the histologic term “pilocytic astrocytoma with fibrillary features” is used to indicate tumors that have all the components of grade I pilocytic astrocytomas but with areas of infiltration suggesting that they could be grade II. Other LGGs include pilomyxoid astrocytomas, oligodendrogliomas, and gangliogliomas. Fibrillary astrocytomas localized to the posterior fossa represent 3% to 15% of cerebellar tumors[533]; their incidence is lower in the remainder of the brain and spine. No gender predilection exists, and the peak age at diagnosis is 6 to 10 years. Genetic abnormalities in LGGs are uncommon.[365] The reported incidence of LGGs has increased during the past several years. Although an association with paternal workplace exposure in the chemical and electrical industries is purported, a more likely explanation is the increased use and availability of MRI and the diagnosis of presymptomatic lesions.[19,534]

Clinical Presentation. The initial symptoms of fibrillary astrocytomas vary, depending on the location of the tumor. Patients with medullary tumors may present with a long history of dysphagia, hoarseness, ataxia, and hemiparesis. Cervicomedullary tumors may cause medullary or upper cervical symptoms such as neck discomfort, weakness or numbness of the hands, and an asymmetrical quadriparesis. Patients with midbrain tumors such as a tectal glioma often present with signs and symptoms of raised ICP. Other symptoms include diplopia and hemiparesis. In children with dorsally exophytic brainstem glioma, a component of the tumor arises in the medulla and expands in a dorsal direction, resulting in noncommunicating hydrocephalus. Supratentorial fibrillary astrocytomas more commonly present with seizures, although thalamic lesions present with motor deficits. Hypothalamic lesions can present as diencephalic syndrome.[520] Low-grade astrocytomas in the brainstem are usually focal rather than diffuse. They tend to arise in the midbrain, cerebellar peduncles, medulla, or cervicomedullary region. Because of the slow rate of progression of these lesions, most patients have subtle neurologic changes that only become evident over a long period. Unlike adult fibrillary astrocytomas, with which degeneration to malignant gliomas is common, pediatric fibrillary astrocytomas remain low grade, even after multiple recurrences.[515,535] Symptoms may exist for months to years prior to the diagnosis of a low-grade astrocytoma.

Imaging and Histology. Most low-grade fibrillary astrocytomas appear isodense on CT without significant contrast enhancement. The tumors are hypointense on T1-weighted and hyperintense on T2-weighted MRI, with minimal or no gadolinium enhancement (Fig. 57-23) except for dorsally exophytic brainstem tumors. This appearance is in contrast to that of most PAs, in which homogeneous contrast enhancement is common. Pathologic examination may demonstrate some cellular pleomorphism, but no mitoses, necrosis, or endothelial proliferation are present (i.e., no histologic features of malignancy are present). Although PAs are usually well-circumscribed lesions with a biphasic pattern of areas of bipolar cells and Rosenthal fibers and other areas with microcysts, fibrillary astrocytomas have greater cellularity and infiltrating boundaries.[536] In contrast to grade III or IV astrocytomas, fibrillary astrocytomas must lack features of malignancy, such as significant atypia and pleomorphism, mitoses, vascular proliferation, and palisading necrosis. A number of other subtypes of grade II astrocytomas have been identified, including the lipoastrocytic,[537] protoplasmic, gemistocytic,[538] and xanthomatous types.[536] These subtypes are much less common in pediatric patients compared with adults, and may have a worse outcome compared with fibrillary astrocytomas and PAs. The rarity of these lesions prevents formal studies of these subtypes.

Management. Management of most fibrillary astrocytomas is similar to that of PAs and depends on the clinical prodrome, age, and location of the primary tumor.[539]

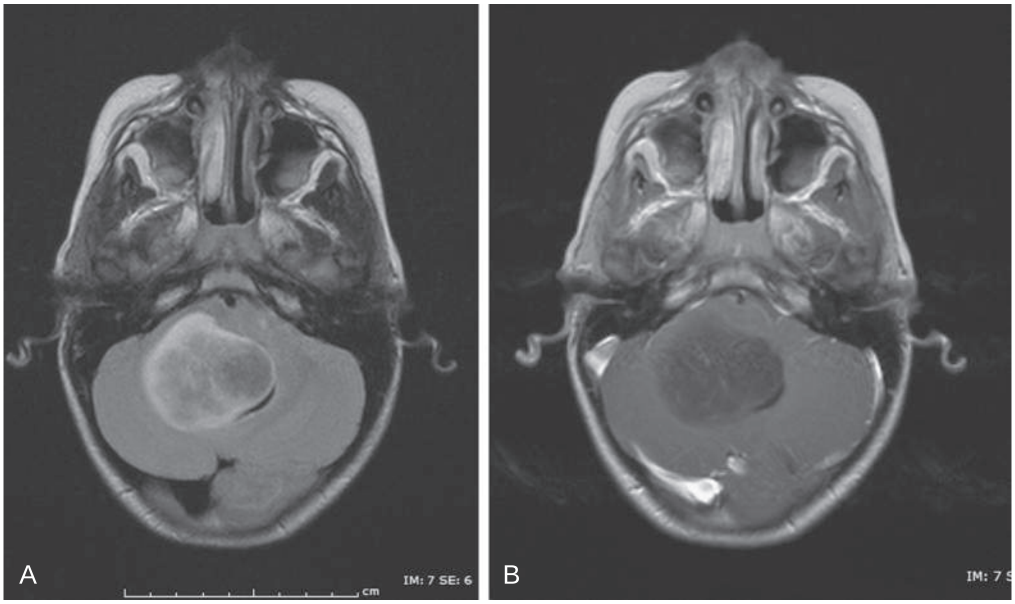

Figure 57-23 Grade II fibrillary astrocytoma. **A,** An axial fluid-attenuated inversion recovery image. **B,** An axial T1-weighted image with use of contrast material showing a noncontrast-enhancing fibrillary tumor.

Rapidly evolving clinical symptoms in the setting of an operable tumor usually warrant prompt neurosurgical intervention. On the other hand, a lesion with a long history of indolent and mild symptoms is often managed with close MRI and clinical surveillance.[468] In patients who subsequently show progressive neurologic symptoms and for whom MRI studies suggest tumor growth, therapeutic intervention is required.[540] Diffuse fibrillary astrocytomas in eloquent locations such as the thalamus or motor regions are often biopsied to confirm the diagnosis and to exclude higher grade glial tumors. They do not lend themselves to radical resections, as is commonly performed for PAs. However in certain cases, such as dorsally exophytic brainstem astrocytomas, radical resection can often confer a long symptom-free outcome. In cases in which resection is not feasible, chemotherapy or radiotherapy may be indicated.[432] As in the case of progressive or unresectable PAs, chemotherapy is the preferred first approach for patients (see Table 57-5).[491,436,541-543] Patients respond well to either vincristine and carboplatin or TPCV chemotherapy. A recent randomized clinical trial of grades I and II astrocytomas has been completed in which these two treatment regimens were compared.[440] Although recurrences occur in most patients, necessitating retreatment with other chemotherapeutic agents, the overall prognosis remains good. Experience with novel combinations of agents[469,450] or high-dose chemotherapy is limited.[460] Radiotherapy is reserved for older children or younger patients whose tumors progress and are refractory to chemotherapy. Reduced radiation doses to adjacent normal tissue, with equivalent tumor control to that of standard photon therapy, can be achieved with conformal proton therapy.[498] Radiation therapy delivered at the time of initial diagnosis does not appear to provide additional benefit for OS.[425]

Prognosis. The long-term survival rate for completely resected pediatric supratentorial low-grade astrocytomas is excellent, especially when compared with similar tumors in adults.[369] Even partially or unresected fibrillary astrocytomas may remain stable for many years. An example of this is the focal midbrain or tectal glioma, which is rarely biopsied or resected.[544,545] Response to chemotherapy appears to be similar to that observed in PAs, although most patients will experience one or more episodes of progression, requiring retreatment with additional chemotherapy.[546,547] However children with primary tumors arising in the pons or thalamus have a worse prognosis.[506,548] The presence of a gemistocytic component characterized by a predominance of large astrocytes, with thick processes and dramatic accumulation of GFAP, represents a histologic variant of low-grade fibrillary (grade II) astrocytoma. This variant may be associated with p53 mutations and may also convey a higher predisposition to malignant transformation.[549,550]

Although most patients with low-grade astrocytomas will survive,[442] patients with fibrillary astrocytomas have a poorer outcome than patients with grade I astrocytomas.[551] Because PAs are more focal and easier to resect than are fibrillary astrocytomas, prognosis may be related to the ease of resection rather than to biologic differences between these histologic variants. Overall survival after chemotherapy of children and adolescents with low-grade astrocytomas at 10 years is 70% to 80%.[425,489,459] The role of MIB1 expression in the prognosis of low-grade astrocytomas is not established as a prognostic factor, after age and degree of resection are excluded.[552] Survivors of low-grade astrocytomas still have a number of limitations.[470,553] Future treatment efforts for these tumors therefore will need to combine effective therapy with improved quality of survivorship in these patients.

Tectal Gliomas

Tectal gliomas are typically hamartomas or low-grade astrocytomas, and patients present with acute hydrocephalus in most cases. These tumors appear to represent a unique variant of low-grade tumors, based on their positive long-term outcome, with relief of hydrocephalus as the sole therapeutic intervention. Because biopsy or surgical resection of these lesions is rarely required, little is known about the pathways that drive their activation. No known genetic syndromes give rise to these tumors.

Presentation. Most patients with tectal gliomas present with the symptoms of obstructive hydrocephalus because of expansion of these lesions adjacent to the periaqueductal space. When the presence of these tumors is picked up incidentally, many patients will demonstrate prolonged periods of stability and do not require treatment.

Imaging and Histology. The radiographic appearance of most tectal gliomas is similar to that of other LGGs. Most tumors lack contrast enhancement (Fig. 57-24). Based on their location and presenting symptoms, histologic verification is not required to make the diagnosis and can cause significant morbidity if attempted.

Management. Biopsy or resection of tectal gliomas is usually not required. Rather, most patients require immediate CSF diversion through a third ventriculostomy.[554,555] Failures of third ventriculostomies have been reported, even many years after the initial procedure, necessitating the proper education of families regarding symptoms that should precipitate immediate evaluation.[556] Reduction in ventricular size is often incomplete and the ventricular size continues to change during the first year after diversion.[557] Rarely tectal gliomas larger than 10 cm at presentation will continue to progress over time and may require surgical debulking and chemotherapy.[558] Tumors that have atypical radiographic features, rapid progression, or repeated recurrence may require a biopsy. Tumors with asymptomatic progression can often be observed carefully.[559] When treatment is required, approaches similar to those used for other low-grade astrocytomas are recommended. Chemotherapy is usually initiated. Radiation therapy is not required for most patients, and continued progression of these lesions into adulthood is rare.

Prognosis. The long-term outcome for patients with tectal gliomas remains excellent, which is surprising given the unresectable nature of the lesion and the absence of therapy for most patients. Overall survival approaches 100% in this population,[560] and thus avoidance of unnecessary surgical or radiation-related long-term morbidity is critical.

Pilomyxoid Astrocytomas

Pilomyxoid astrocytomas are a newly stratified group of grade II pediatric tumors in the 2007 WHO classification[207,361] that were previously grouped together with PAs.[561,562] Although no specific molecular pathway responsible for these tumors has yet been identified, the presence of defects in the *BCR* gene on chromosome 17[563] provides possible clues that require further analysis. Other chromosomal aberrations have also been identified.[564] Pilomyxoid astrocytomas are found most commonly in the midline of the brain and spine.[565] These tumors are usually identified in infants and young children, although their presence in adults has been

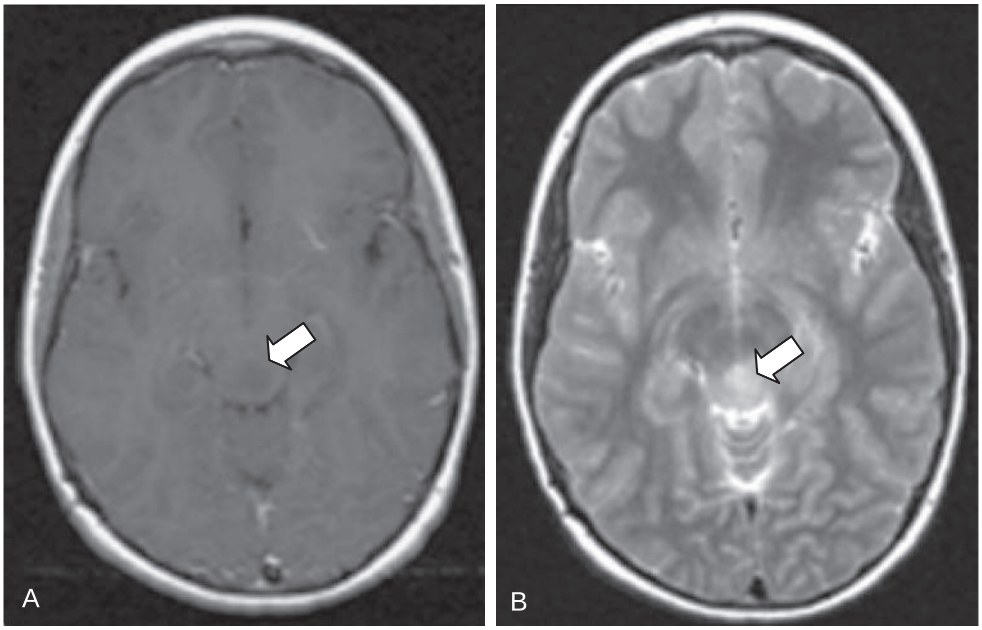

Figure 57-24 Tectal glioma. **A,** An axial T1-weighted image with use of contrast material showing a noncontrast-enhancing tectal tumor *(arrow)*. **B,** An axial T2-weighted image shows T2 hyperintense lesion in the tectum *(arrow)*.

reported.[566] At recurrence, tumors can appear as classic PAs, suggesting a developmental relationship between the two types of tumors.[567]

Clinical Presentation. Although pilomyxoid astrocytomas present in a manner similar to that of other LGGs, the incidence of metastatic disease at presentation appears higher and requires a full workup, including spinal MRI and CSF for cytologic evaluation. Patients with pilomyxoid astrocytomas may be at greater risk for spontaneous hemorrhage at the time of diagnosis or resection or during follow-up.[568,569]

Imaging and Histology. On MRI pilomyxoid astrocytomas appear similar to PAs, with well-circumscribed margins and little peritumoral edema.[570] They are usually found in the midline, including the brainstem[571] and spine,[572] and can be solid or solid and cystic. They are usually bright on T1- or T2-weighted and FLAIR sequences, and they enhance with administration of contrast material.[573] In approximately 50% of cases, the contrast enhancement is heterogeneous.[574,575] Adjacent areas of brain can demonstrate elevated choline-to-creatinine ratios suggestive of an infiltrative margin.[575] Although their location, young patient age, and increased presence of dissemination provide clues to the diagnosis before a biopsy is performed, imaging characteristics do not clearly differentiate these tumors from other LGGs in the pediatric population.[576] Histologically these lesions lack many features of PAs, such as Rosenthal fibers and a biphasic pattern. Rather a monophasic pattern and myxoid background is seen, with strong GFAP and synaptophysin staining.[577] Like other glial tumors, mixed lineages may also be possible for pilomyxoid astrocytoma.[578] The variable histologic appearance compared with PAs,[579] MRS signal changes,[580] and a higher incidence of progression and dissemination support their distinction from PAs.[561] A predilection for younger age appears to exist when the tumor is localized to the pituitary-hypothalamic region.[581]

Management. Because of the more aggressive nature of these tumors compared with PAs, pilomyxoid astrocytomas are now classified as grade II gliomas. Treatments typically follow those of other LGGs, including vincristine and carboplatin and TPCV chemotherapy. Other therapies used for PLGGs have also been used for patients with pilomyxoid astrocytomas (Table 57-5).[582,583] Upfront chemoradiation therapy combinations have also been tried for these tumors.[584] Formal clinical trials for this rare subtype are not possible, however. Because of the young age of the patient and the deep location of these tumors in many patients, radiation-based strategies will lead to significant long-term morbidity in most survivors. Many patients with pilomyxoid astrocytomas are infants and have diencephalic syndrome with dissemination, and thus complete surgical resection is not possible. Thus most patients will start with LGG chemotherapy. The use of intrathecal therapy for patients with disseminated disease who are unable to receive craniospinal radiation can be considered.

Prognosis. Without well-defined studies, the prognosis of pilomyxoid astrocytoma is difficult to assess with certainty. Confounding issues of deep-seated lesions, especially around the hypothalamic region in which surgical options are limited, along with the young age of these patients and the presence of metastatic disease, likely affect the overall poor prognosis. A mean OS of 60 months for patients with pilomyxoid astrocytoma versus 220 months for patients with grade I PAs has been reported.[581] Whether their unique biology affects survival is unknown, although these tumors can recur as typical grade I pilocytic astrocytomas.[567] As in other LGGs, nestin expression may correlate with a worse prognosis.[585]

Ganglioglioma and Glial-Neuronal Tumors

Gangliogliomas are low-grade (WHO grade I) glioneuronal tumors. These tumors represent 4% to 8% of primary brain tumors in children, with 80% occurring before age 30 years and at a mean age less than 10 years.[586] These tumors are frequently associated with seizures and tend to grow slowly. Gangliogliomas can occur throughout the CNS,[587,588] although most are localized to the temporal and parietal lobes.[586] A significant proportion of these tumors have the BRAF V600E mutation,[388,411,413,589] which is now being targeted in open international clinical trials. The presence of this oncogenic mutation may result is a more aggressive behavior and worse outcome.[590]

Clinical Presentation. Seizures are the first manifestation in 50% of cases of ganglioglioma, and many patients have a prolonged history of seizures of longer than 2 years.[586] Complex partial seizures are common because gangliogliomas are frequently located in the temporal lobe, particularly the temporomesial region,[591] although they can occur anywhere in the brain or spine.

Imaging and Histology. Gangliogliomas are typically contrast-enhancing cystic lesions on CT scans. The MRI appearance of these tumors can be variable but is frequently hypointense on T1-weighted sequences and hyperintense on T2-weighted images. Gadolinium enhancement varies in intensity from absent to significant and can be nodular, solid, or circumferential.[592] An infantile variant of ganglioglioma, desmoplastic infantile ganglioglioma (DIG), can occur (discussed later). Pathologic studies show synaptophysin and neuronal nuclear antigen (NeuN)–positive ganglion cells, as well as a GFAP-positive astrocytic component.[593] Lesions associated with the ganglion cell but lacking the astrocytic component are called gangliocytomas. Gangliogliomas are frequently WHO grade I tumors, although some may show anaplastic features in the glial or neural component.[594,595] MIB1-positive cells are usually localized to the astrocytic component.[596] Glial-neuronal tumors likely represent a spectrum of LGGs that include gangliogliomas and may also have PI3K pathway activation.[597]

Management. Complete or near-total resection is the treatment of choice[591] and, in most cases, can eliminate or significantly improve seizure frequency in this patient population.[598,599] Recurrent or unresectable tumors may be treated with radiation therapy,[586,600,601] although these lesions may respond to LGG chemotherapy, and thus patients may avoid some of the long-term toxicity of radiation.[459] In the case of recurrent or unresectable ganglioglioma, response to LGG chemotherapy has been demonstrated.[586] Treatment for recurrent or unresectable gangliogliomas is included in current LGG chemotherapy trials. It should be noted that these tumors have been shown to undergo malignant transformation over time, usually involving the astrocytic component. Clinical trials of BRAF V600E inhibitors are under way for persons with this mutation, and significant durable responses have been reported.[305]

Prognosis. GTR is often curative, making tumor location and extent of resection the most important prognostic factors.[591] Most patients are rendered seizure-free after GTR.[599] Gangliogliomas of the posterior fossa have also been reported, and their outcomes appear to be similar to those for supratentorial lesions. Patients whose tumors can be fully resected to remove the enhancing components are likely to remain disease free, although persons with subtotal resected disease often require additional resection, chemotherapy, and/or radiation therapy.[587] The uncommon presentation of these tumors in the infratentorial location and the limited sample sizes in case reports limit the confidence with which therapeutic approaches can be recommended. Spinal cord ganglioglioma appear to have an indolent course. Patients with subtotal resection can remain stable for prolonged periods. Therefore treatment should be deferred until lesions show clear evidence of progressive disease.[602] Very rarely, gangliomas and glial neuronal tumors can degenerate into a CNS PNET (the neural component) or into a malignant glioma (the astrocytic component).

Desmoplastic Infantile Gangliogliomas

DIGs are supratentorial tumors involving the leptomeningeal surface and are identified predominantly in children younger than 2 years,[603] although reports in older children are available.[604] These lesions are often very large, in part because of the presence of cysts, and they frequently involve the dura. Although precise estimates of their incidence are lacking, they make up fewer than 1% of pediatric brain tumors. A number of chromosomal abnormalities have been reported, although only in a small number of cases, particularly at chromosome 7q31 (corresponding to *MET* gene). One case containing the BRAF V600E mutation was also noted in this series[605] and was reported in two other patients in a different analysis.[606]

Clinical Presentation. Most patients present with increasing head circumference, bulging fontanelle, and lethargy. Older patients present with focal motor deficits.

Imaging and Histology. DIGs are large cystic structures on CT scans, with contrast enhancement of the solid component. T1-weighted MRI sequences demonstrate an isointense tumor; T2-weighted intensity of the tumor is variable. The tumors usually enhance after administration of contrast material. Peritumoral edema is uncommon. DIGs possess a desmoplastic stromal background, with neoplastic neurons and astrocytes. They often have areas with an elevated MIB1 labeling index, although this characteristic does not usually represent transformation to a more malignant phenotype.[607] Tumors lacking the neural component are called desmoplastic infantile astrocytomas.

Management. Cure can be achieved with complete resection. Many patients have remained progression-free after total resection without additional treatment.[608] Chemotherapy, as for other low-grade astrocytomas, can be considered for patients with symptomatic or progressive cases for whom surgical removal is not feasible.[593,609]

Prognosis. Most patients will be long-term survivors if a complete resection is achieved.[608] Lesions that are more deep-seated may have a poorer outcome, and initiation of chemotherapy may be considered at the first signs of progression in these unresectable tumors.[603,610] Metastatic lesions have been reported, suggesting that in rare cases, a more malignant phenotype can occur.[593,611]

Dysembryoplastic Neuroepithelial Tumors

DNETs are recently described tumors that may comprise as many as 1% of all brain tumors in patients younger than 20 years.[612] Two thirds of all DNETs are located in the temporal lobe, and DNETs are found in 5% to 15% of temporal lobe resections for intractable epilepsy. These lesions are classified as WHO grade I tumors.[613] Thought to be developmental in nature, they are treated with surgery. They are considered to have limited proliferative potential, suggesting that complete surgical resection is not required for long-term disease control[614]; nonetheless, recurrences can occur.[615]

Clinical Presentation. The diagnosis of DNET should be a consideration in children and young adults with new-onset seizures or a long history of epilepsy. Patients with these tumors typically present with a long history of complex partial seizures, with an average age of onset of 9 years. In many patients the seizures are refractory to anticonvulsant medications. The superficial cortical location of DNETs may account for the high risk of seizures.

Imaging and Histology. Contrast-enhanced cranial MRI typically shows a temporal or frontal lobe lesion, absent peritumoral edema, and only minimal, if any, gadolinium enhancement. The tumors are bright on T2-weighted sequences and hypointense on T1-weighted images (Fig. 57-25). Mass effect is minimal to absent. Although routine fluorine 18–labeled deoxyglucose–PET imaging has not been helpful in the preoperative identification of these lesions, Carbon 11–methionine–PET was able to distinguish these lesions from other low-grade lesions.[616] The pathologic findings include a specific glioneuronal element manifested by GFAP-negative oligodendroglia-like cells and neurons in a mucinous eosinophilic background that give the appearance of floating neurons.[617] Because

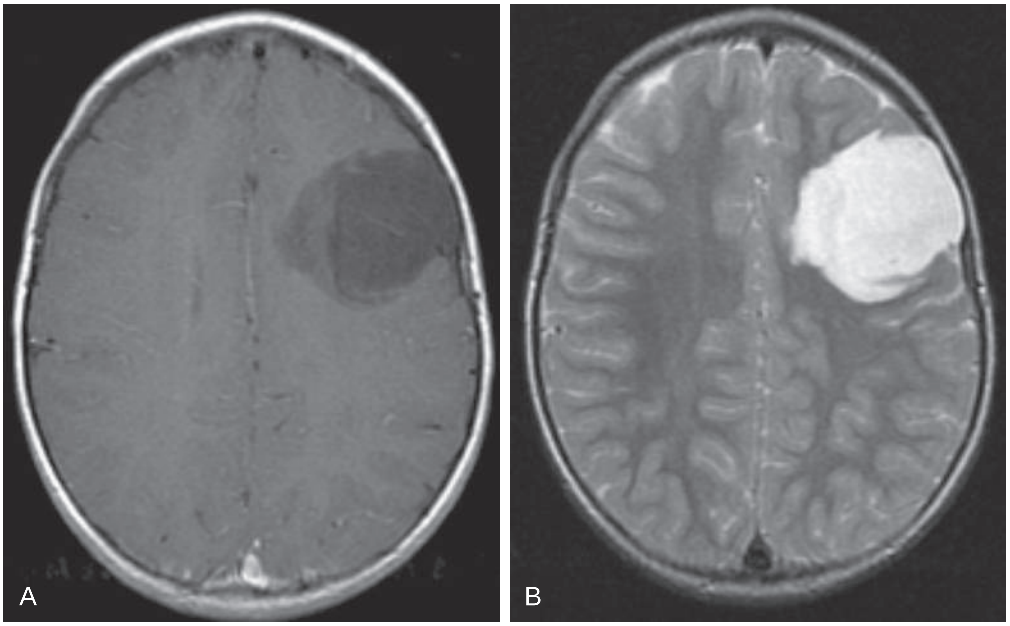

Figure 57-25 Left frontal dysembryoplastic neuroepithelial tumor. **A,** An axial T1-weighted image with use of contrast material showing a large nonenhancing tumor. **B,** An axial T2-weighted image.

oligodendrocytes, astrocytes, or both are found on histopathologic analysis, the pathologic differential diagnosis often includes oligodendroglioma, mixed oligoastrocytoma (OA), and ganglioglioma. Like gangliogliomas and PXAs, DNETs have been reported to have the BRAF V600E mutation in approximately 30% of cases.[618] Differentiation of DNETs from other LGGs can be difficult.

Management. Although these tumors have a benign course, the associated seizures may be refractory to antiepileptic drugs because of the increased expression of multidrug transporters.[619] Gross total resection is often curative and typically alleviates the seizures, especially if the areas of cortical dysplasia can also be removed,[620] although some case series have shown a significant number of patients who continue to have residual seizures.[614,615] Adjuvant chemotherapy or radiation therapy is not recommended. Rare cases of malignant transformation of DNETs after radiation and chemotherapy have been reported.[621]

Prognosis. The stable behavior of these tumors over time results in an excellent prognosis after gross total or partial resection.[614] Patients often have improved seizure control after surgery, especially if a complete resection was achieved,[622] and some improvement in neuropsychologic functioning has been observed.[623]

Pleomorphic Xanthoastrocytomas

Pleomorphic xanthroastrocytomas (PXAs) are uncommon grade II cortical tumors that mainly occur in children and adolescents and account for fewer than 1% of CNS tumors. The median age at the time of diagnosis is 14 years. The molecular pathogenesis of these tumors is poorly understood, and no causative chromosomal abnormalities have been identified. The BRAF V600E activating mutation has been detected in more than 50% of cases, and drugs targeting this mutation are now in clinical trials.[412,413] A recent analysis of 50 PXAs by comparative genomic hybridization, however, has revealed that loss of chromosome 9 is the most common chromosomal lesion.[624] A few reports of PXA in conjunction with NF-1 may implicate the Ras pathway in this disease.[625]

Clinical Presentation. PXAs are typically large and superficially located, especially in the temporal lobes. Seizures are the most common presenting feature. For tumors of the cerebellum, pineal region, or spine, direct nerve compression results in focal deficits, and obstruction of CSF flow results in raised ICP.[626] Rare cases of dissemination have been reported.[627,628]

Imaging and Histology. PXAs typically manifest enhancement on MRI, with occasional intratumoral cysts and calcification (Fig. 57-26). Peritumoral edema is uncommon. Tumors usually extend to the meninges. The typical histopathologic picture includes a pleomorphic appearance of the astrocytic component, with significant cellular atypia and bizarre multinucleated giant cells with intracellular lipid accumulation. The proliferative indices are usually low, although necrosis, endothelial proliferation, and mitoses have been described. PXA can be confused with glioblastoma multiforme[629] because of the presence of multinucleated cells and occasional foci of necrosis.[630] The expression of CD34 on most tumors may be useful in the histologic classification of difficult or atypical cases.[631] Prognosis appears to correlate with MIB1 expression.[632] In lesions with mitoses, an elevated MIB1 labeling index, and necrosis, the term “pleomorphic xanthoastrocytoma with anaplastic features” is used.

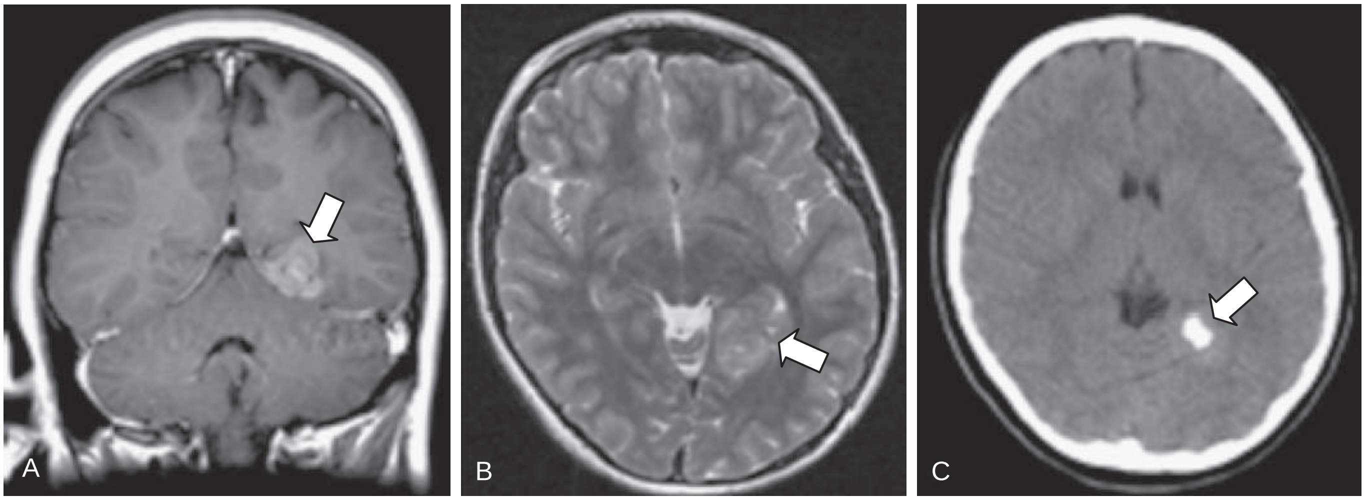

Figure 57-26 Pleomorphic xanthoastrocytoma. **A,** A coronal T1-weighted image with use of contrast material *(arrow)*. **B,** An axial T2-weighted image *(arrow)*. **C,** A noncontrast computed tomography image *(arrow)*.

Management. The clinical diagnosis of PXA should be suspected in children who present with new-onset seizures, focal deficits, and a large, enhancing cortical mass on brain imaging. The goal of surgery is to achieve a GTR, which is usually curative.[633,634] Adjuvant therapy can be deferred, although the patient should be followed expectantly. Tumors that recur and incompletely resected lesions with anaplastic features may be treated with chemotherapy[635] or radiotherapy,[636] although significant activity for these modalities has not been demonstrated. Few formal clinical trials for this rare subtype have been performed.

Prognosis. Several series have reported a 5-year PFS of greater than 70%. However the presence of mitoses, endothelial proliferation, or necrosis on the pathologic specimen, although rare, may significantly alter the clinical behavior and prognosis.[632] Cases of anaplastic PXA with subsequent malignant transformation have been reported.[637,638] Radiation therapy does not alter the poor outcome in these cases.

Subependymal Giant Cell Astrocytomas

SEGAs usually originate in the ependymal walls of the lateral ventricles and are associated almost exclusively with TS, an autosomal-dominant disorder.[639] Patients with TS have hamartomas and benign tumors of multiple organs, including the brain. The CNS manifestations include cortical tubers (hamartomas), subcortical glioneuronal hamartomas, subependymal glial nodules, and subependymal giant cell astrocytomas.[640] Two genetic defects, one in the *TSC1* gene on chromosome 9q and the other in the *TSC2* gene on chromosome 16p, account for TS. Sporadic cases are rare.[641]

Clinical Presentation. SEGA is sometimes the presenting feature of TS in patients without the typical physical stigmata of the syndrome. Because of the variable phenotype of TS, a consensus on diagnostic criteria has been developed. Presentation in older children and adolescents is common. Although patients with TS typically have multiple periventricular SEGAs, those that produce symptoms of hydrocephalus arise in close proximity to the foramen of Monro, although lesions around the pineal gland can also result in symptoms.[642] Most patients with known TS are followed up with regular neuroimaging and the SEGAs are removed serious neurologic syndromes, such as headaches, altered sensorium, or weakness are present.[324] Of note, patients with TS may have other significant neurologic symptoms, such as seizures and cognitive deficiency related to cortical tubers.[643]

Imaging and Histology. CT and MRI are essential for early and accurate diagnosis. Although CT is superior to MRI for detecting small calcified lesions, MRI is superior to CT for identifying areas of gliosis, heterotopia, and SEGAs, which have the typical radiographic appearance of candle dripping.[644] SEGAs typically show diffuse contrast enhancement on CT and MRI studies (Fig. 57-27).[90] SEGAs are considered grade I astrocytomas. They are well-circumscribed tumors that are positive for GFAP, neurofilament, neuron-specific enolase, and synaptophysin.[645,646] Mitoses can be identified but do not indicate a higher grade or more malignant phenotype. They can occasionally be associated with bleeding.[647]

Management. The management of patients with TS is complex and requires adherence to recent consensus conference guidelines.[648] GTR is the treatment of choice for SEGAs that are progressive, and cause obstructive hydrocephalus[649] or seizures.[650,651] The major risk of surgery is injury to the forniceal columns, resulting in memory disturbance. The benign behavior of these tumors warrants reoperation in the case of recurrence or progression after subtotal resection. Inhibition of the mTOR pathway in SEGAs has resulted in a very high response rate, and mTOR inhibitors have now been approved for the treatment of these lesions.[93,652]

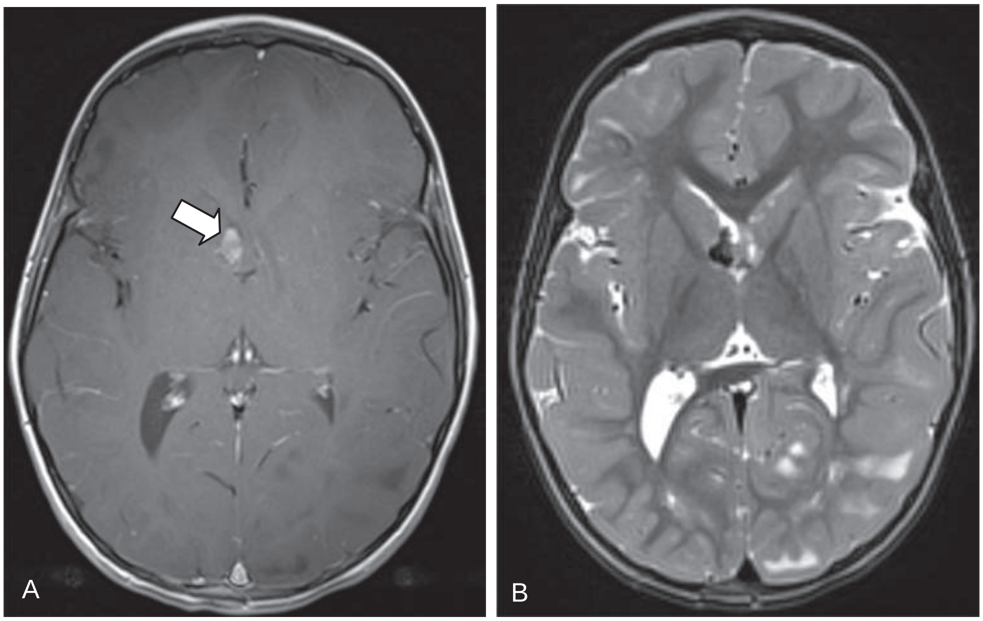

Figure 57-27 Subependymal giant cell astrocytoma. **A,** An axial T1-weighted image with use of contrast material showing an enhancing tumor *(arrow)*. **B,** An axial T2-weighted image showing an area of dark signal corresponding to tumor.

Prognosis. SEGAs are essentially benign tumors, and gross total resection is generally curative. However multiple tumors may arise in some patients with TS, requiring ongoing radiologic surveillance.[90] The overall prognosis for patients with TS is good, despite increased susceptibility to other tumor types, including rhabdomyomas of the myocardium and angiomyomas of the kidney, liver, adrenals, and pancreas.[653]

Hemangioblastomas

Hemangioblastomas are WHO grade I lesions associated with von Hippel-Lindau (VHL) disease. They occur primarily in adults and are centered in the cerebellum, brainstem, and spinal cord.[654] Although sporadic tumors can arise, pediatric cases are usually associated with the inherited syndrome. Cases associated with VHL disease can be single or multifocal, although most sporadic cases involve isolated nodules. Hemangioblastomas are highly vascularized lesions, although the genetic defect is localized to the stromal elements rather than the vasculature.[655] Tumor development appears to be related to the deregulation of VEGF. Patients with hemangioblastomas need to undergo complete genetic evaluation for VHL disease and, for those with the inherited disease, careful lifelong screening is necessary.[656]

Clinical Presentation. Obstruction of CSF flow is the primary reason for symptomatology in patients with VHL disease who are diagnosed with hemangioblastomas. Headaches, morning vomiting, and long tract signs are therefore common. Ataxia and cranial nerve dysfunction can also be observed.[657]

Imaging and Histology. Hemangioblastomas are typically well-circumscribed cystic lesions with a solid tumor nodule. The solid component tends to enhance brightly with contrast and is usually located peripherally within the cyst (Fig. 57-28). Flow voids are commonly observed on MRI and can be well delineated with angiography. Peritumoral edema is commonly observed. Tumors are usually composed of two elements—the stromal cells, which express vimentin and VEGF, and the endothelial cells, which express the VEGF receptor VEGFR2. Hemangioblastomas typically have low proliferative levels based on MIB1 immunoreactivity and are considered grade I tumors.

Management. The management of these tumors requires specialized neurosurgical expertise because of the high risk of bleeding. The primary approach to these lesions, which tend to occur most commonly in the posterior fossa and cervicomedullary area, is maximal surgical resection.[656] This approach provides long-term control in most patients,[658] although, because of the underlying genetic predisposition, new tumors may continue to develop throughout the life of the patient. Embolization can reduce the intraoperative risks of bleeding.[659,660] Radiosurgery can successfully treat the mural component of these tumors, although control is negatively influenced by the presence of the cysts.[661] VEGF inhibitors have been tested in this population with initial encouraging results, although follow-up of these reports is still pending.[662] A case of prolonged stable disease with thalidomide treatment was reported, although whether this outcome was related to its antiangiogenic or immune modulatory effects is unknown.[663]

Prognosis. Because of the genetic basis of these lesions, recurrences are common and likely represent new tumors rather than recurrences of previously resected ones, which

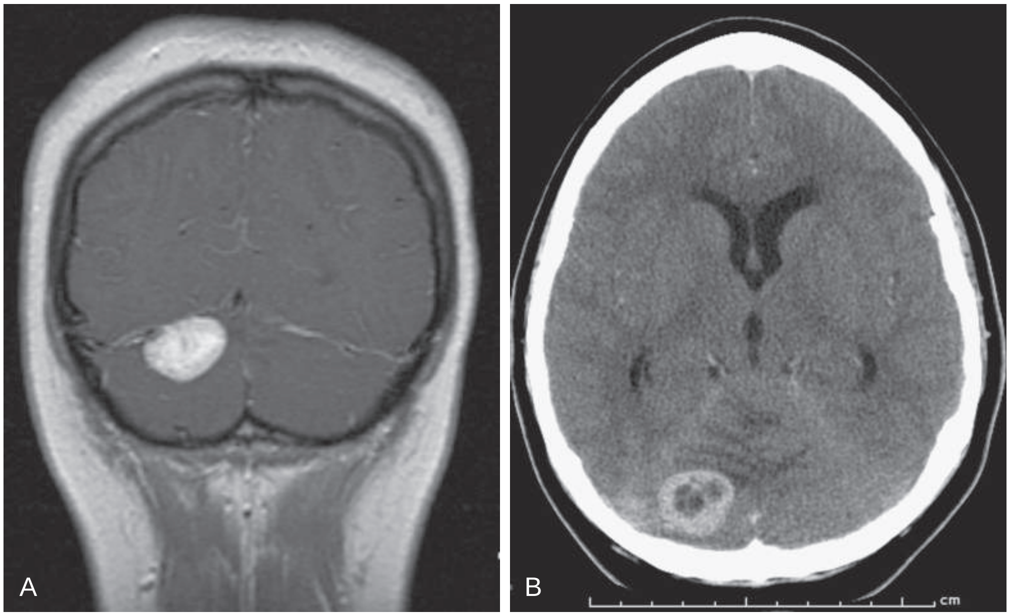

Figure 57-28 Cerebellar hemangioblastoma. **A,** A coronal T1-weighted image with gadolinium. **B,** A computed tomography image.

indicates the importance of continued careful evaluation in this patient population.

Rare LGGs

Tanycytic Astrocytomas. Tanycytic astrocytomas are rare and poorly characterized tumors. They are most common in adults and usually occur in the hypothalamic region.[664] Their malignant potential is not well defined, although recurrences after complete resection have been observed. One reported case occurred in the context of an adolescent with NF-2.[665]

Lipoastrocytomas. Lipoastrocytomas are rare cortical tumors that, as the name suggests, possess fat droplets that give them the appearance of adipocytes in the context of a low-grade astrocytic lesion. These tumors express GFAP.[537] Recurrences can occur and are treated with resection. Malignant transformation has not been reported in this tumor type, although one case was identified on autopsy in a patient with diffuse intrinsic pontine glioma.[666]

Dysplastic Cerebellar Gangliocytomas. Dysplastic cerebellar gangliocytomas are rare tumors of the cerebellum and fourth ventricle region that are of limited proliferative potential. They have a characteristic imaging pattern on MRI, with an abnormal laminated pattern in the cerebellum, although this pattern is not pathognomonic and can be mimicked by medulloblastoma. As such biopsy is recommended to differentiate the two entities.[667] Dysplastic cerebellar gangliocytomas do not typically require therapeutic intervention, although seizure activity can occur as a result of their presence.[668]

Disseminated Oligodendroglial-Like Leptomeningeal Tumor of Childhood. Disseminated oligodendroglial-like leptomeningeal tumor of childhood is a newly described entity that typically demonstrate leptomeningeal enhancement on MRI and associated cystic or nodular T2 hyperintense lesions within the spinal cord/brain along the subpial surface. A discrete intraparenchymal lesion, usually in the spinal cord, is found in the majority of cases. These tumors are thought to have a greater risk of malignant transformation.[669]

High-Grade Astrocytomas

High-grade astrocytomas (HGAs) encompass anaplastic astrocytoma (WHO grade III) and glioblastoma (previously glioblastoma multiforme, WHO grade IV) of the brain and spinal cord. This category also includes as a subgroup DIPG, even though these tumors occasionally show lower grade histology. HGAs, unlike LGGs, are much less common in children than adults. Whereas more than 30% of all pediatric brain tumors are LGGs, non-DIPG HGAs represent only 6% to 12% of all primary pediatric brain tumors, and DIPGs represent another 10%. In the past several years, many key discoveries have been made about the biology of these tumors, and increasingly, important distinctions from adult HGA biology are being found.[670] Unfortunately major treatment advances have not yet followed the biologic discoveries, and most children with these tumors eventually succumb to their disease. Because of key differences between DIPGs and other pediatric HGAs, most notably in prognosis and management, DIPG is discussed separately from the remainder of tumors in this category.

Supratentorial HGAs (Excluding DIPG). Although adult and pediatric HGAs are similar histologically, increasing evidence indicates key biologic differences, even within shared pathways of tumorigenesis. Common pathways include the overexpression or mutation of EGFR,[671] although both changes are less frequent in pediatrics,[672] activation of the PI3K signaling pathway via silencing of the PTEN tumor suppressor,[673-675] most often by methylation in pediatrics,[676] and the MGMT DNA repair pathway, which is commonly methylated in adult HGAs but is more often overexpressed in pediatric tumors,[677,678] perhaps helping to explain TMZ resistance in children with HGAs.[342]

Recent findings have also demonstrated involvement of new pathways and features of pediatric HGA, further distinguishing them from adult tumors. These new pathways include overexpression of PDGFRα[679,680] and novel histone mutations in *H3F3A* (observed in a minority of these tumors vs. a majority of DIPGs).[681,682] Comprehensive profiling of HGA genetics has shown gains in chromosome 1q in pediatric HGA on copy number analyses,[683,684] which is unusual in adults; fewer cases show chromosome 7 gain and 10q loss, two features seen in the majority of adult HGAs.[684] One study appeared to show two distinct gene expression profiles in pediatric HGA, one that is similar to adult HGA, and one that is divergent.[685] The PARP DNA repair pathway is also overexpressed in many pediatric HGAs,[686] and this feature is associated with a poor prognosis[687]; PARP inhibitors may be useful as radiosensitizers.[687] Aurora kinase B is overexpressed in a majority of pediatric HGAs.[688] Unlike in adults, *IDH1* mutations have not been found in pediatric HGAs.[689] Pediatric tumors have demonstrated abnormalities in the Ras and Akt pathways, as well as Y-box protein-1.[690,691] Microsatellite instability, which has been associated with a number of adult tumors, is very rare in pediatric HGAs.[692-694]

Overexpression of many proteins distinguish pediatric HGAs from LGGs, including the DNA repair protein insulin-like growth factor binding protein 2 (IGFBP2),[695] the cancer-testis antigen and possible immunotherapy target NY-ESO-1,[696] the p53 inhibitor HDMX,[697] the angiogenic marker endoglin,[698] and the catalytic subunit of human telomerase reverse transcriptase (HTERT)[699]; the differentiation marker NF1A is underexpressed in pediatric HGA compared with LGG.[700] In the CCG study of children with malignant HGGs (CCG945), p53 status was an important independent prognostic variable, with a 5-year PFS of 44% in tumors expressing a low level of p53 versus 17% in those overexpressing p53.[701] Finally new epigenetic findings in pediatric HGAs include hypermethylation of the LIM homeobox 9 (LHX9) transcription factor,[702] downregulation of class II and IV histone deacetylases (HDACs),[703] acetylation of histone H3.3,[703] and a decrease in adenosine deaminase, ribonucleic acid (RNA)-specific, 2 (ADAR2)–mediated RNA editing.[704]

Clinical Presentation. The clinical manifestations of HGAs depend on the anatomic location and the age of the patient. The clinical prodrome is usually short and rapidly evolving, with signs and symptoms of elevated ICP and focal neurologic deficits. A protracted course may evolve in the usual case of malignant transformation of a low-grade glioma,[705] but in general, transformation of low-grade gliomas to high-grade gliomas is extremely rare in children, unlike in adults. Dissemination of HGA into the cerebrospinal fluid is less common than for medulloblastoma and other neural tumors but is being recognized more frequently,[706] particularly as patients survive longer. Approximately 3% of pediatric patients with an HGA will have CNS metastatic disease at presentation.[707]

Imaging and Histology. Typical HGAs have an MRI appearance of heterogeneous enhancement or diffuse nonenhancing tumor with significant edema on the T1-weighted image, compressing or displacing adjacent ventricular structures and occasionally causing hydrocephalus. The T2-weighted signal is often more diffuse, consistent with both infiltrative tumor and edema (Fig. 57-29). MRS demonstrates a markedly elevated choline-to-NAA ratio; a 40% increase in choline over normal brain tissue indicates an HGA with 90% sensitivity and specificity. Lesions tend to be ^{18}F-labeled deoxyglucose–PET avid, although ^{18}F-fluoro-ethyl-tyrosine (FET)–PET may be superior for treatment planning and distinguishing between LGGs and HGAs.[708,709] Technetium 99m–sestamibi SPECT (MIBI SPECT) imaging can also detect

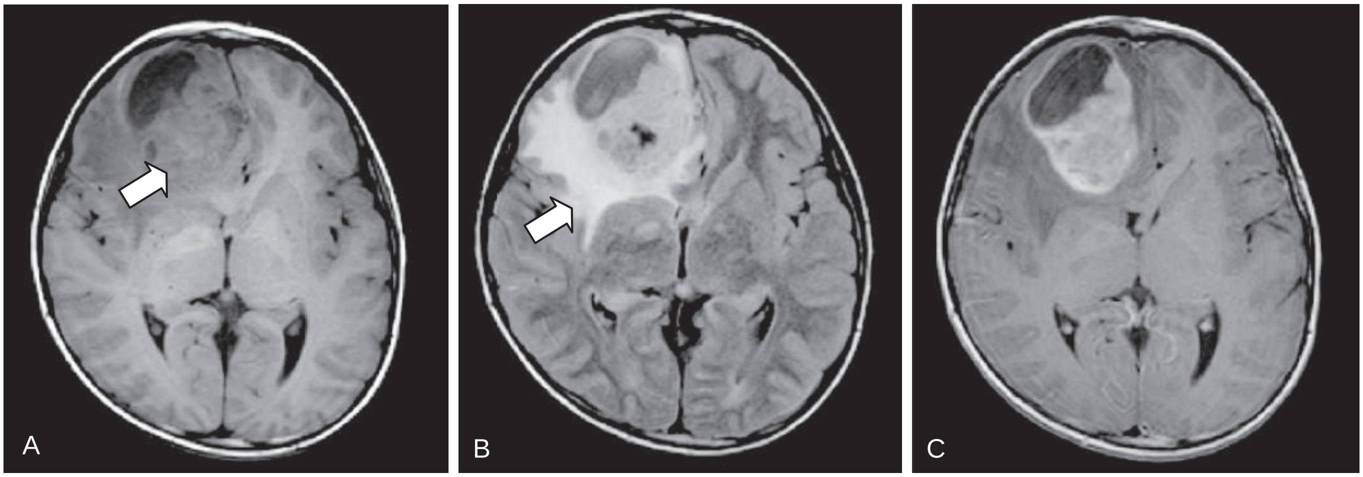

Figure 57-29 Right frontal glioblastoma. **A,** An axial T1-weighted image without use of contrast material showing the tumor *(arrow)*. **B,** An axial fluid-attenuated inversion recovery image showing peritumoral edema and infiltrating tumor *(arrow)*. **C,** An axial T1-weighted image with use of contrast material.

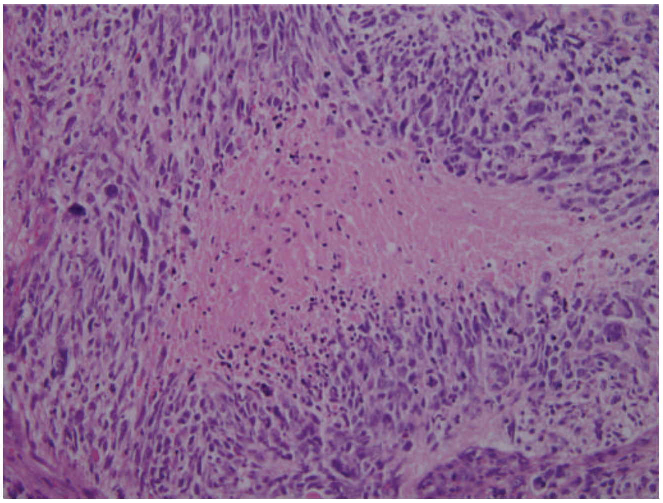

Figure 57-30 Palisading necrosis in a child with glioblastoma (hematoxylin and eosin; ×400).

HGAs and can be used to follow up for response or recurrence,[174] as can serial diffusion weighted assessment.[710] Areas of hemorrhage within pediatric HGAs at diagnosis are not uncommon.[711] The presence of an HGA within the volume of a previously irradiated field is difficult to differentiate from a radiation-induced high-grade transformation of a low-grade astrocytoma, although preliminary studies have identified some molecular differences distinguishing radiation-induced glioblastoma.[712] Malignant features on histopathologic examination of HGA include nuclear pleomorphism, mitoses, palisading necrosis (Fig. 57-30), endothelial proliferation (Fig. 57-31), and a high Ki-67 or MIB1 labeling index (see Fig. 57-17), although high interobserver variability exists between pathologists in judging these features.[713] Most pediatric HGAs are nestin-positive on immunohistochemistry.[714] Distinguishing between grade III and IV tumors relies on differences in histologic features; all HGAs must demonstrate nuclear atypia and mitoses, whereas grade IV tumors must also show either endothelial proliferation, necrosis, or both. It has now been shown that a proportion of CD133+ HGA cells costain for CD105 (endoglin), an angiogenesis marker, suggesting that vasculogenic mimicry occurs in pediatric HGAs, which may help increase angiogenesis in HGA through the formation of fluid-conducting vessels of tumor cells. CD105 staining is an unfavorable prognostic marker.[698]

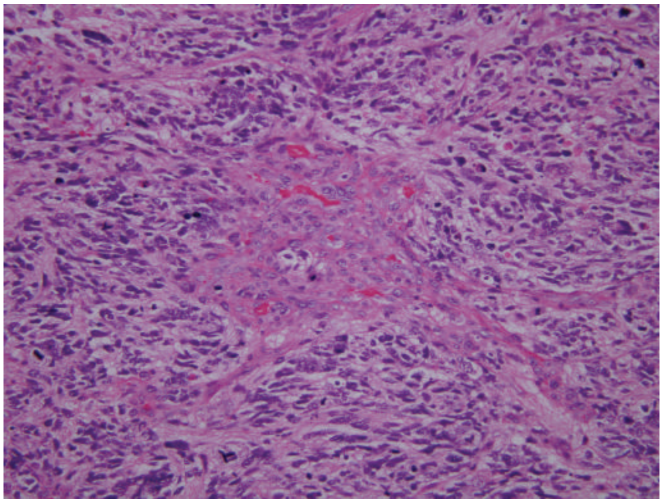

Figure 57-31 Vascular proliferation with a glomeruloid tuft in a child with glioblastoma (hematoxylin and eosin; ×400).

Management. The initial management of pediatric HGA after neuroimaging is to administer high-dose corticosteroids to achieve symptomatic relief. Subsequently the goals of neurosurgery include establishing a histologic diagnosis and, whenever possible, achieving GTR.[715] GTR is often not possible given the infiltrative properties of HGA, but even subtotal resection that achieves internal decompression or debulking makes subsequent radiotherapy more tolerable and probably more effective, given the lower tumor burden. Resection also diminishes the duration of corticosteroid therapy.[716] Intraoperative MRI appears to increase the likelihood of GTR.[717] The role of radiation therapy in the treatment of older children has been clearly established during the past 30 years,[718,719] and the current standard in patients 3 years of age and older is a conformal dose of 5400 cGy to the primary tumor volume with a boost to 5940 cGy in the tumor bed.

Ever since the first national randomized trial comparing radiation versus radiation with chemotherapy in pediatric HGAs (CCG-943) showed a survival benefit for patients treated with chemotherapy, the use of adjuvant chemotherapy has been standard in the treatment of pediatric HGAs.[720] However subsequent trials have failed to show a similar benefit, and the role of chemotherapy in the disease remains unclear. One area of recent focus has been the use of TMZ, which has become the standard of care in adult HGA. However a primary pediatric HGA phase II trial of concomitant TMZ and radiation therapy, followed by adjuvant TMZ, failed to show an improvement in overall or EFS compared with historic control subjects.[721] Other phase II trials of the mTOR inhibitor temsirolimus,[722] the VEGF inhibitor bevacizumab,[723] and TMZ in combination with the DNA repair inhibitor O6-benzylguanine,[338] all in recurrent or progressive pediatric HGA, also failed to meet their aims. Radiosensitizers, including inhaled carbogen, have also failed to show efficacy.[724] A strategy that has shown potentially more promise is multiagent chemotherapy, with or without ASCR. Multiagent, multicourse chemotherapy with radiation therapy improved survival over historic control subjects in patients with primary HGA who had undergone GTR.[725] Another trial of multiagent chemotherapy given over a long period showed promise in delaying radiation therapy for patients with HGA who were younger than 3 years, given the especially severe neurodevelopmental effects of radiation in this age group.[726] Treatment with high-dose chemotherapy and ASCR has also been attempted in this group.[727,728] The risk-benefit ratio is still under investigation,[729] with initial reports of a 23% overall response but a mortality rate of 16%.[730] A trial of high-dose thiotepa and carboplatin followed by ASCR produced one long-term survivor out of four children treated for recurrent or progressive HGA; remission at the time of treatment appeared to be a key positive prognostic factor in this trial, which also included children with high-grade nonastrocytic brain tumors.[507]

Clearly, further study of the role of chemotherapy in pediatric HGAs is needed, as are new strategies. A current COG trial is comparing three potential chemotherapy regimens (the HDAC inhibitor vorinostat, TMZ, and bevacizumab) to be given with radiation therapy, followed by maintenance chemotherapy with TMZ and bevacizumab. Recent phase I trials have used the EGFR inhibitor erlotinib[731] and a prolonged dosing schedule of TMZ.[732] An autologous dendritic cell–based vaccine has shown potential efficacy.[733] Oral valproic acid has shown some effect retrospectively and is well tolerated, making it an attractive potential additive agent for future trials.[734] New mouse models of pediatric HGA inspire hope for more effective preclinical testing that could help bring more novel treatments to clinical trials.[735,736]

Prognosis. The prognosis for children with HGA is poor but is better than for adults.[737-739] The degree of surgical resection is associated with better PFS.[740,741] Patients with anaplastic astrocytoma have a more favorable prognosis than those with glioblastoma.[742,743] A report from the CCG[740] showed that the 5-year PFS rates for anaplastic astrocytoma were 44% ± 11% and 22% ± 6% for children who underwent GTR versus other types of surgery, respectively. The 5-year PFS rates for glioblastoma were 26% ± 9% and 4% ± 3% for children who underwent GTR versus other types of surgery, respectively. Patients younger than 3 years appear to have a survival advantage compared with older patients.[744] One study showed worse PFS for patients initially treated with dexamethasone, raising the question of whether tumor inflammation may be important to treatment.[745] Poor performance at diagnosis on the FMH health status scale correlates with a worse prognosis.[746] The size of the treating medical center has no effect on prognosis.[747] In terms of biologic markers, PTEN expression[748] and MGMT methylation[749] favorably affect survival, whereas p53,[701] endoglin,[698] and PARP[686] positivity are negative prognostic markers. MIB1 staining is usually elevated in pediatric HGA and correlates with grade and prognosis. Patients with MIB1 levels greater than 36% had a 5-year PFS of 11% compared with 33% in persons with MIB1 levels less than 18%.[742]

SPECIAL CASES. HGAs occur more commonly in persons with certain genetic syndromes. These syndromes include hereditary nonpolyposis colorectal carcinoma[104] and Li-Fraumeni syndrome, a dominantly inherited syndrome involving mutations of the p53 tumor suppressor protein.[750] *TP53* mutations are rare in sporadic pediatric CNS tumors lacking a typical family history.[751] HGAs may also arise in persons with NF-1, although low-grade lesions are far more common; in one large case series, HGAs developed in 0.5% of patients.[752]

Cases of de novo congenital HGAs have been observed at birth or within the first 3 months of life and show similarities in gene expression profiling compared with both pediatric and adult HGA.[753] Prognosis, however, appears to be far better. Long-term survival, occasionally even without treatment,[754] occurs in the majority of these patients and supports the unique characteristics of these otherwise fatal tumors.[738,755-759]

Thalamic gliomas can occur as high-grade or low-grade lesions.[516] Poor prognostic factors in these patients include a short interval of symptoms, poor early response to chemoradiotherapy, high-grade histology, and inability to resect the lesion.[515,760] For spinal HGA the median age of presentation is 4 years. Positive prognostic factors include age younger than 5 years, anaplastic astrocytoma histologic features, lack of hemorrhage, and GTR.[761] Multimodality treatment may have some effect.[762] Another rare subtype of pediatric glioblastoma is giant cell glioblastoma. Although time to progression in this variant may be slightly longer, overall prognosis is not significantly better than in other pediatric HGAs.[763]

Gliosarcomas are glioblastomas with a sarcomatous component that can affect children of any age but seem to be most frequent in infants and toddlers, as well as patients who have received prior radiation therapy. They most often present with increased ICP and are located in the cerebrum. Gliosarcoma also carries a poor prognosis.[764] Optic nerve gliomas show HGA features on pathologic examination in approximately 17% of patients. School-aged children are most often affected. The 5-year OS rate is approximately 20% with high-grade histologic features, apparently irrespective of treatment with radiation or surgery.[765]

Diffuse Intrinsic Pontine Gliomas

Tumors of the brainstem occur in approximately 10% of pediatric patients with CNS tumors. The majority of these tumors, approximately 80%, are classified as DIPG and are infiltrative, expansile lesions of the pons. Most of these tumors are anaplastic astrocytoma or glioblastoma on histopathologic examination, although grade II DIPG has been reported; the dismal prognosis is not affected by grade.[766,767] This diagnosis must be distinguished from other pediatric brainstem tumors[768] that are usually WHO grade I, well circumscribed as opposed to infiltrative, and carry a much improved prognosis. The median age at diagnosis of DIPG is 5 to 9 years, but these tumors may occur throughout childhood.

Lack of understanding of DIPG biology was a major roadblock in the past, mostly because researchers had minimal tissue to study because these tumors were rarely biopsied; the procedure was believed to be highly morbid. In addition many samples that were obtained were from areas at the periphery of the tumor and included normal cells and reactive gliosis. Even autopsy specimens were rare. However in more recent years, two major trends have emerged. First, researchers determined that obtaining DIPG tissue by autopsy was feasible, and provided an opportunity that families of these children generally greatly appreciated and did not regret.[769-772] This tissue, generally preirradiated, led to new DIPG culture lines[769] and biologic studies. Second, new neurosurgical techniques emerged, along with targeted therapies based on initial biologic studies,[773] that could be offered to families who consented to upfront biopsy so that patients' tumors could be tested for susceptible genetic changes.

With tissue available, studies of DIPG biology have emerged at a rapid pace. One theme across several studies is amplification of the region containing PDGFR alpha (PDGFRA),[684,774] and protein expression analysis has confirmed the importance of PDGFRA deregulation in DIPG.[684] Thirty-six percent of DIPG samples in another study had PDGFRA amplification, far more than in pediatric and adult HGA.[775] Another key finding has been the discovery of novel mutations in *H3F3A*, encoding histone H3.3, or histone cluster 1, H3b *(HIST1H3B)*, encoding histone H3.1.[776] These mutations were isolated by whole genome sequencing of DIPG samples. Of note, the *H3F3A* mutation was also found in 22% of nonbrainstem pediatric HGAs but was not found in adult HGAs. In a subsequent study in which investigators looked for these mutations in a targeted manner, it was found that the H3.3 mutation occurred in 71% of DIPGs.[681] Although the biologic consequences of this mutation are not yet clear, it does seem to correlate negatively with prognosis.

Other new findings have included overexpression of Aurora kinase B,[688] WEE1 G2 checkpoint kinase (WEE1),[777] B7-H3 (CD276),[778] and interleukin (IL)-13Rα2.[779] Common mutations have been found in TP53, PI3K catalytic subunit (PI3KCA),[780] and EGFR, which surprisingly showed expression of the vIII mutant in a majority of cases, although confirmation of this finding is needed.[781] Authors of one study suggested two biologic subgroups of DIPG, one driven by proangiogenic changes and one driven by PDGFRA amplification or mutation; this latter group seemed to have more deaths before 10 months from diagnosis.[782] Finally, with establishment of a plausible cell of origin that depends on the hedgehog pathway,[783] as well as development of new preclinical models including mouse intracranial xenograft models,[784,785] further understanding of the disease should be forthcoming.

Clinical Presentation. The clinical presentations of children with brainstem tumors appear to fall into two groups. Patients with fewer than 3 months of symptoms, multiple cranial neuropathies (unilateral or bilateral), long tract signs (e.g., Babinski sign, hyperreflexia, and weakness), and cerebellar signs (e.g., ataxia, dysmetria, and dysarthria) are likely to have DIPG. Symptomatic hydrocephalus is present in fewer than 10% of patients with DIPG at presentation. Although the pons is not typically associated with behavior changes, pathologic laughter or separation anxiety have been symptoms noted in persons with DIPG.[786] In contrast children with low-grade brainstem gliomas tend to manifest a more insidious history of isolated cranial nerve palsy or weakness, usually for longer than 3 months.

Imaging and Histology. The diagnosis of DIPG may be made on the basis of the classic MRI appearance of a diffusely expanded pons with encirclement of the basilar artery.[787] Most DIPGs appear to be hypointense on T1-weighted MRI and hyperintense on T2-weighted imaging. A prominent edema signal is common (Fig. 57-32). The ventral pons may appear swollen and infiltrated. Contrast enhancement is variable, from homogeneous rim enhancement to patchy enhancement to complete absence of enhancement. In contrast to DIPGs low-grade focal lesions of the brainstem present with a more circumscribed appearance and associated contrast enhancement that occupies less than 50% of the axial diameter of the brainstem. These tumors may be composed of cystic and solid components. Leptomeningeal dissemination at diagnosis and recurrence may be more common in DIPGs than previously understood,[788] and given the negative effect on prognosis, spine MRI at diagnosis should be considered. Diagnosis by imaging alone puts DIPG in a unique category, apart from nearly every other pediatric tumor, and some studies showing variability in reading of MRIs have called the practice into question.[789] Another study of MRI-biopsy correlation showed that all diffuse, nonenhancing tumors were DIPG pathologically, whereas the diagnosis was more variable with focal or enhancing tumors.[790]

New MRI techniques have been found to have specific roles in diagnosing DIPGs. DTI is helpful in differentiating DIPG from demyelinating disease when the diagnosis is in question.[791] Susceptibility-weighted imaging appears to be the best technique for detecting hemorrhages in DIPGs, which appear to be present in 47% of patients at diagnosis, although most hemorrhages are petechial and asymptomatic.[792] MRS has identified a specific spectrum consistent with the malignant potential of DIPG. More importantly this method can detect positive responses in patients after radiation therapy, as well as changes indicative of progression in advance of MRI changes.[793] The Cho : NAA ratio and lactate measurement on MRS appear to correlate with the length of survival.[794,795] Elevated tumor perfusion on MRI after radiation therapy appears to predict a longer OS, and perfusion has been shown to decrease prior to clinical progression.[796] Serial measurement and estimation of response may be best achieved with FLAIR imaging,[797] although no radiologic methodology is optimal for disease assessment or response. Time to progression or OS, rather than radiographic response, may therefore be the best determination of treatment activity in clinical trials for this population.[798] Ventriculomegaly without obstruction appears to be a common finding after radiation therapy in persons with DIPG, suggesting communicating hydrocephalus.[799]

The histologic appearance of DIPG is similar to that of other HGAs.[800] Most biopsy samples show evidence of atypia and mitoses and qualify as grade III anaplastic astrocytomas. Differentiation between anaplastic astrocytoma and glioblastoma in the pons is not relevant because all these patients appear to have an equally poor outcome.

Management. During the past 30 years, little progress has been made in the treatment of DIPG.[801] Radiation therapy has improved the median OS from weeks to months, but it can at best be considered palliative therapy. Despite many clinical trials, no chemotherapeutic agent has shown an improvement compared with radiation alone. Few patients survive more than 2 years.[802]

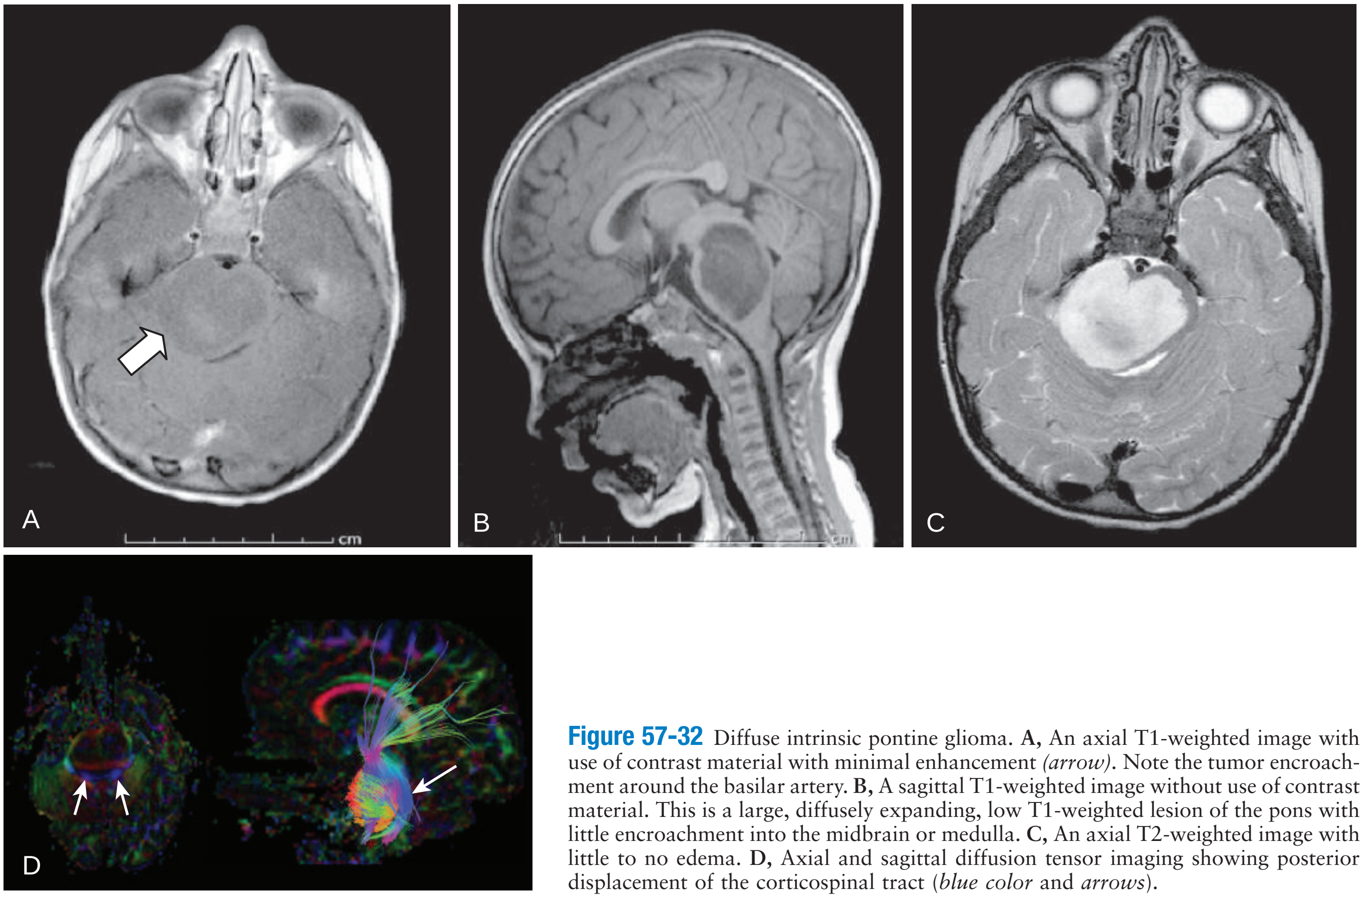

Figure 57-32 Diffuse intrinsic pontine glioma. **A,** An axial T1-weighted image with use of contrast material with minimal enhancement *(arrow)*. Note the tumor encroachment around the basilar artery. **B,** A sagittal T1-weighted image without use of contrast material. This is a large, diffusely expanding, low T1-weighted lesion of the pons with little encroachment into the midbrain or medulla. **C,** An axial T2-weighted image with little to no edema. **D,** Axial and sagittal diffusion tensor imaging showing posterior displacement of the corticospinal tract (*blue color* and *arrows*).

Corticosteroids are generally started at the time of diagnosis, because peritumoral edema may contribute significantly to symptoms, and steroids may therefore offer some relief. Patients with DIPG often require steroids for a long duration, and investigation of agents that can offer relief from peritumoral edema without the adverse effects of steroids is ongoing.

The tide is clearly shifting toward diagnostic biopsy in patients with suspected DIPG. Several retrospective studies of open and stereotactic biopsy showed that the procedure is feasible and safe.[803-805] A prospective trial of 24 patients undergoing stereotactic biopsy showed that transient cranial nerve palsies in two children were the only complications, with tissue obtained in all patients, including two for whom the biopsy results changed the management approach.[806] A consensus statement in support of biopsy on behalf of a large group of DIPG experts has now been published.[807] The procedure still carries risk, however, and should be performed at experienced centers by experienced neurosurgeons. The ideal locations for stereotactic biopsy appear to be areas of focal anaplasia, represented by T2 hypointensity, contrast enhancement, and diffusion restriction.[808]

Radiation therapy remains the mainstay and standard treatment for DIPG. The tumor volume and a 1- to 2-cm volume of surrounding brainstem are generally included in the field, and conventional doses range from 5400 to 5940 cGy given over 6 weeks. This treatment is generally effective at decreasing tumor size, decreasing symptoms, and allowing patients to stop taking steroids, but these effects generally last only a matter of months, and the treatment is still considered palliative instead of curative. Multiple studies have attempted hyperfractionation techniques, ranging from 6600 to 7800 cGy, without improvement in survival[809-815]; this outcome may relate to the inherent resistance of these tumors.[816] More recently in an attempt to reduce the impact of the radiation therapy schedule for these children with a limited life span, hypofractionation schedules have been tested, usually 3900 to 4500 cGy over 3 to 4 weeks, with a noninferior response rate and duration.[817,818] Reirradiation is also the only therapy that has shown any potential efficacy at recurrence: two retrospective reports showed transient responses of some patients to reirradiation doses of 1800 to 2000 cGy, with children who had a prolonged duration of response from initial radiation therapy most likely to benefit.[819,820]

Many adjuvant chemotherapy agents and strategies have been tried and have failed to improve outcomes in patients with DIPG compared with radiation therapy alone. Many recent phase II trials have centered on the use of TMZ, given that this agent is now standard of care in adults with HGG. However three phase II trials of TMZ given with radiation therapy, followed by TMZ alone, have failed to show an increase in survival time compared with historic standards from radiation therapy alone,[721,821,822] and the addition of TMZ worsened toxicity. Other recent phase II trials have shown no benefit of tamoxifen,[823] pegylated interferon α-2b,[824] a regimen of cisplatin, etoposide, ifosfamide, vincristine, and valproate,[725] and inhaled carbogen as a radiosensitizer.[724] Other past failed agents and strategies have included preirradiation multiagent chemotherapy,[825,826] topotecan as a radiosensitizer,[827,828] etanidazole as a radiosensitizer,[829] chemotherapy concurrent with radiation therapy including thalidomide,[830] trofosfamide and etoposide,[831] carboplatin,[832] carboplatin and etoposide,[833] TMZ and cis-retinoic acid,[834] chemotherapy with BBB disruption,[835] intraarterial bevacizumab injection,[836] and a postradiation high-dose chemotherapy regimen.[837] New strategies that have been the subject of recent phase I reports include the use of the PDGFR inhibitor dasatinib in combination with the VEGFR2 inhibitor vandetanib,[838] vandetanib alone,[839] and the use of arsenic trioxide.[840] The development of nonhuman primate models of direct drug delivery into the brainstem opens another avenue for developing improved therapies for these tumors.[841,842]

Prognosis. DIPG remains the most challenging of pediatric tumors to cure. Despite all approaches most survival curves are superimposable with regard to OS.[843] Meta-analyses of numerous clinical reports indicate that median PFS ranges from 5 to 9 months, with a median OS of 6 to 16 months. One-year and 2-year survival ranges from 17% to 50% and 7% to 29%, respectively, with less than 10% survival at 3 years.[843,844] Neither MRI characteristics nor WHO grade has an impact on prognosis in persons with DIPG.[845] Poor performance at diagnosis on the FMH health status scale correlates with a worse prognosis.[746] The size of the treating medical center has no effect on prognosis.[747] One report indicated an improved prognosis for patients with DIPG who are younger than 3 years,[846] although questions of misclassification of patients with low-grade brainstem glioma as having DIPG inevitably arise with reports of improved survival—yet another reason for the use of diagnostic biopsy. Very few cases of neonatal DIPG have been reported, and outcomes in these reports have been inconsistent, ranging from spontaneous regression to death within weeks.[847-849] Retrospective studies have shown worse prognoses for patients initially treated with dexamethasone or rofecoxib, raising the question of whether tumor inflammation may be important to treatment.[745,850] Patients with leptomeningeal dissemination at diagnosis appear to have a shorter PFS than do patients who do not have this finding.[788] It is hoped that with time, the greatly improved understanding of DIPG biology and promising preclinical models will soon lead to successful clinical trials and an improved outlook for patients afflicted with this terrible disease.

Gliomatosis Cerebri

Although much more common in adults, gliomatosis cerebri has also been identified in children.[851] Similar to adults, in children these lesions are often grade III astrocytomas that diffusely infiltrate the brain and appear to favor white matter tracts,[852] and they can easily cross the corpus callosum. In spite of the widespread presence of disease, often involving both hemispheres and multiple lobes, a large primary focal mass is usually absent. All parts of the brain and spine can be involved. The overall prognosis is very poor by virtue of the disease's diffuse nature and unresectability.[853] Patients can be kept alive with palliative care for longer than would be expected for widely diffuse lesions, suggesting a different biology from that of typical grade III astrocytomas.[854] Genetic aberrations, including loss of chromosomes 13q and 10q or gains of chromosome 7q, have been shown to be markers of poor outcome.[855] Some tumors demonstrate abnormalities in the p53 pathway.[856,857] Recently IDH1 mutations have also been found in adult but not pediatric gliomatosis cerebri.[858]

Clinical Presentation. The clinical presentation of children with gliomatosis cerebri is varied and often subtle, mimicking a number of neurologic conditions.[859,860] Children present more frequently than adults with refractory seizures that can be palliated with surgical intervention.[861] Other presentations of this disease include raised ICP and cognitive impairment.[862] Tumors involving the brainstem can result in cranial nerve deficits, and those in the optic pathway can present with visual field deficits.

Imaging and Histology. Gliomatosis cerebri is diagnosed on MRI scan and demonstrates a characteristic diffuse infiltrative pattern.[863] T1-weighted sequences are usually isointense to hypointense and underestimate the extent of disease, whereas T2-weighted sequences are hyperintense and highlight the full extent of the disease (Fig. 57-33). Signal abnormality usually involves multiple lobes.[864] The presence of contrast enhancement is strongly correlated with a poorer prognosis in both adult and pediatric patients.[854,855] A solid area of tumor is usually not evident. MRS demonstrates elevation of choline and a decrease in NAA levels.[865] Although the hallmark of gliomatosis cerebri is an infiltrative astrocytic tumor, areas of oligodendroglial cells are not uncommon for adult and pediatric patients.[866,867] Most tumors are consistent with grade III histology, and mitoses are often present. MIB1 staining can vary considerably. The absence of mitoses is more likely to be because of sampling error. GFAP and S-100 can be positive or negative. Nestin and vimentin can be positive.[868] Because of their infiltrative growth and co-opting of existing blood vessels, these tumors lack the abundant neovascularization observed in other malignant gliomas,[869] which suggests that they will not be effectively treated with antiangiogenic agents.

Management. Currently patients with gliomatosis undergo biopsy to confirm the diagnosis. Given the diffuse nature of these tumors, complete resection is rarely feasible. The mainstay of therapy is irradiation to the involved region, which, for pediatric patients, may require almost complete whole-brain therapy. In addition to significant morbidity, large-volume radiation therapy for

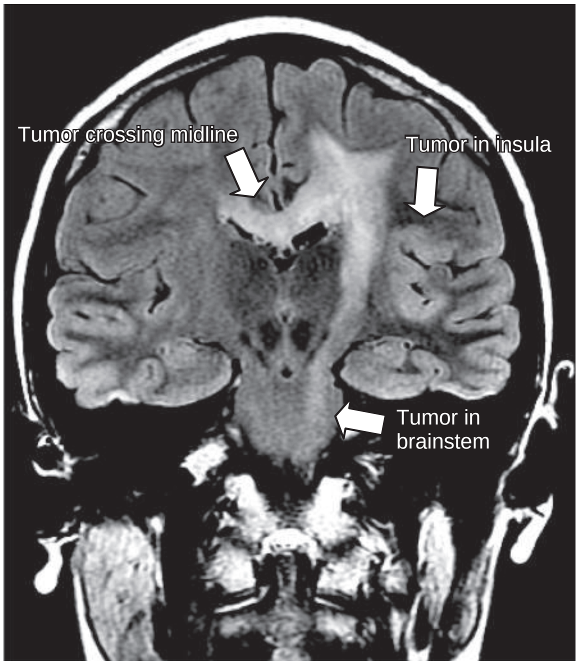

Figure 57-33 Gliomatosis cerebri. This coronal fluid-attenuated inversion recovery image demonstrates the diffuse infiltration. Note that a solid uniform mass is absent.

gliomatosis cerebri has not been proven to be effective,[867] although it may delay the time to progression.[870] Objective responses to TMZ have been documented in adults[871,872] and, in oligodendrogliomas, correlate with chromosome 1p and/or 19q loss.[873] The impact of MGMT expression on response and outcome has not yet been determined.

Prognosis. Pediatric patients with gliomatosis cerebri have a poor outcome.[853,854] In a large series of pediatric and adult patients, a median survival of 14.5 months was demonstrated. Younger age, lower grade histology, and chemoresponsiveness were associated with slightly longer survival times.[874] Although long-term survival is unlikely, adults whose tumors have chromosomal 1p and/or 19q loss can show more chemoresponsiveness to agents such as TMZ.[855] Similar activity in pediatric patients has not been reported because of the rarity of these tumors in this population.

Ependymomas

Ependymomas are glial tumors that arise from ependymal cells that line the ventricles in the CNS. Ependymal cells play an essential role in the transport of CSF. Experimental evidence has indicated that these cells may be derived from radial glia.[875,876] Ependymal tumors represent approximately 10% of all childhood intracranial neoplasms, constituting the third most common pediatric brain tumor, after astrocytomas and medulloblastoma. They are equally distributed between males and females, and the median age at diagnosis is approximately 6 years. They are significantly less common in blacks than whites.

Ninety percent of pediatric ependymomas are intracranial, with 66% to 75% arising from the posterior fossa.[877] Supratentorial ependymomas are often located in the brain parenchyma, away from the ependymal surface, in contrast to infratentorial ependymomas, which are usually located in relation to the fourth ventricle. Spinal cord ependymomas represent fewer than 10% of pediatric intramedullary spinal tumors. In contrast ependymomas represent more than 50% of intramedullary spinal tumors in adults.[878]

The WHO classification system[879] recognizes four major types: subependymoma and myxopapillary ependymoma (WHO grade I), classic ependymoma (WHO grade II), and anaplastic ependymoma (WHO grade III). Differentiation of grade II and grade III ependymoma does not clearly have an influence on outcome,[880] in contrast to the grade in astrocytic tumors. Subependymomas are well circumscribed, slow-growing, and often asymptomatic intraventricular neoplasms that are usually found incidentally in middle-aged and older adults or at autopsy. Myxopapillary ependymomas (WHO grade I) are also slow-growing tumors of the conus medullaris, cauda equina, and filum terminale and manifest primarily in young adults. They account for approximately 10% of all ependymomas and portend an overall good prognosis with surgery-only approaches.

Recent advances in molecular studies have found that ependymomas from different compartments of the brain and spine have unique molecular signatures with distinct patterns of gene expression,[881] chromosomal changes, and protein expression.[882] Deletion of tumor suppressor P16INK4A (located at chromosome 9p21.3) was frequently observed in supratentorial ependymoma. Witt et al[883] analyzed the transcriptome of 177 patients with posterior fossa ependymoma and proposed two distinct subtypes of posterior fossa ependymoma based on different clinical and molecular characteristics (i.e., age, tumor location, degree of genomic instability, alterations in molecular pathways, and prognosis). The "pediatric" subgroup (median age of 2.5 years), designated as group A in the study, showed relatively less genomic instability but commonly harbored chromosome 1q gain and 22q loss. A balanced genomic profile and chromosome 1q amplification have been previously described as two of three defining molecular features of posterior fossa ependymoma.[884,885] The older subgroup (median age of 20 years), designated as group B, exhibited a much higher degree of genomic instability and extensive cytogenetic aberrations. Interestingly a balanced genomic profile, seen in the pediatric subgroup, was paradoxically associated with a worse prognosis. Posterior fossa ependymomas in young children were much more likely to recur, metastasize, or result in mortality. Even accounting for whether GTR was achieved, group A tumors exhibited worse PFS and OS compared with group B (18% 5-year PFS and 52% OS in group A vs. 91% 5-year PFS and 100% OS in group B; $P < .0001$).[882,883] The identification of immune markers in these analyses may provide important opportunities for the development of immunotherapy-based treatments.[886] Chromosome 22q loss is commonly associated with spinal ependymoma in adults and children.[887,888]

The most consistent genetic defects in ependymoma are monosomy 22 or structural abnormalities of chromosome 22q,[889] which raises the possibility that a tumor suppressor gene may be located on chromosome 22.[890-892] As previously noted, comparative genomic hybridization has demonstrated significant differences between infant and childhood ependymoma, suggesting that the pathogenesis of this disease differs by age[893] and location.[894] A number of other molecular defects have been described in ependymomas, including the abnormal expression of ERBB2 and ERBB4 receptors,[895] defects in the p53 homologue p73,[896] increased expression of the VEGF protein,[897] Nestin expression,[898] PI3K activation,[899] immune targets such as EphA2, IL-13Rα2, and Survivin,[900] amplification or overexpression of the p53 regulator MDM2,[901] overexpression of cyclooxygenase-2 (COX-2),[902] the presence of telomerase activity,[903,904] and expression of protein 4.1.[905] Other molecules implicated in the pathogenesis of ependymoma have been reported by using micro RNAs[906] and proteomic fractionation of tumor tissue. Future studies will be required to determine the significance of these molecules and their potential use as diagnostic markers and targets for therapy.[306]

Significant progress has also been made in the use of these markers in attempting to understand and characterize the putative ependymoma stem cell[907,908] with expression of OLIG2.[909] The role of telomerase may also be an important factor in the recurrence of ependymomas,[910,911] and additional markers are being developed.[891,912] The advances in assessment of the epigenome of ependymoma have also recently been reported and give important clues about the role of DNA methylation in the genesis and possibly targets of ependymoma.[913-915] Finally, the presence of JC (John Cunningham) viral sequences identified in 5 of 18 ependymomas (but 0 of 32 medulloblastomas) raises the possibility that this agent is associated with ependymal tumorigenesis.[916] Simian virus 40 (SV40) viral, large, T-antigen sequences have also been identified in ependymomas and choroid plexus papillomas (CPPs)[917] but are negative in adjacent normal brain.[918] Although these results have generated significant discussion, they have not been confirmed.[919,920] Further studies will be needed to validate these findings.

In myxopapillary ependymoma, a WHO grade I ependymoma that is confined to the conus medullaris-cauda equina-filum terminale of spinal cord, upregulation of 20 members of the homeobox (HOX) family that are not typically observed in intracranial ependymoma has been described.[921] EGFR has also been identified in ependymomas of the brain[922] and myxopapillary ependymoma and correlates with progression.[923]

Persons with NF-2 have an increased susceptibility to intramedullary spinal cord ependymomas.[924] Although the *NF2* gene is located at chromosome 22q12, mutations in *NF2* (Merlin) are rarely found in sporadic ependymomas.[925,926] A recent microarray analysis of pediatric ependymomas has identified a cluster of genes distinct from *NF2* that may be involved in ependymoma tumorigenesis.[891] Expression profiling has indicated that histologically similar ependymomas from different parts of the CNS are molecularly and clinically distinct disease subgroups.[875,927] Certain familial colon cancer syndromes may also be associated with an increased incidence of ependymoma in offspring.[928]

Clinical Presentation. The presenting symptoms of infratentorial ependymomas are a result of their origin from ependymal tissue lining the fourth ventricle. Hydrocephalus results when the tumor fills the fourth ventricle, causing obstruction of the normal spinal fluid flow and subsequent development of headache, irritability, nausea, vomiting, and ataxia. Papilledema can often be found on physical examination. Tumors that extend out of the foramen of Luschka may compromise lower cranial nerve function and cause hearing impairment, hoarseness, and/or dysphagia. If the tumor extends through the foramen of Magendie, the patient may report neck discomfort or be noted to have torticollis. The most common signs of the tumor in infants are irritability, decreased oral intake, vomiting, ataxia, head pain, lethargy, and increased head circumference.[929] Supratentorial ependymomas which represent approximately one third of ependymomas, are more common in older children and adults. These patients present with focal neurologic deficits and seizures. Spinal ependymomas are typically located in the cervical region. The most common presenting symptom is pain or motor deficits localized to the level of the spinal cord lesion. The pain is typically described as being worse at night, presumably because of congestion of the spinal venous plexus that occurs when the patient is in the recumbent position. The second most common symptom is radicular dysesthesias, and a late manifestation of this symptom is progressive spastic quadriparesis. Thoracic ependymomas are associated with scoliosis. Myxopapillary ependymomas of the conus medullaris and filum terminale may cause low back pain, radicular pain, saddle anesthesia, and sphincter dysfunction.[930] When these tumors disseminate, they usually remain in the spine,[931] although cranial metastases have been reported; therefore craniospinal imaging at diagnosis should be undertaken.[932] Pediatric myxopapillary ependymoma may have a higher propensity to spread compared with adult tumors.[932]

Imaging and Histology. A typical MRI appearance of a fourth ventricular ependymoma is that of a homogeneously enhancing well-circumscribed solid mass, extending out one of the foramina of Luschka or Magendie with obstructive hydrocephalus. These tumors classically wrap around the brainstem or herniate through the foramen magnum (Fig. 57-34). Hemorrhage and calcifications can be observed and are more common in supratentorial lesions. Ependymomas may occasionally spread via CSF, seeding the leptomeninges or ventricles, either at diagnosis or at recurrence.[933] Careful attention to staging of patients is therefore important.

The characteristic microscopic feature of a classic ependymoma is that of dense cellularity, intermixed with perivascular pseudorosettes consisting of tumor cells and surrounding a neoplastic blood vessel (Fig. 57-35). True ependymal rosettes representing abortive canals are relatively uncommon.[934] Histologically the anaplastic variant is recognized by the presence of mitoses, necrosis, and

vascular proliferation. They tend to be more cellular than grade II ependymomas but usually remain well demarcated. MIB1 rates greater than 5% in incompletely resected tumors or greater than 15% in completely resected tumors correlate with more aggressive behavior.[935] GFAP and S-100 are positive in most ependymomas, and epithelial membrane antigen (EMA) stains are positive in anaplastic variants. The presence of perivascular elastic fibers may also be a diagnostic feature of these tumors.[936] In patients in whom the diagnosis of ependymoma is indeterminate, electron microscopic analysis of cilia structure and junctional complexes, which are found in most ependymomas, can be used to confirm or exclude the diagnosis. Myxopapillary ependymomas have a mucinous appearance and arise almost exclusively in the cauda equine.[930] Their MIB1 labeling index is typically low. Tanycytic ependymomas are a rare subtype of ependymoma that can occur throughout the brain or spine.[664,937] Other rare subtypes include cellular ependymoma, papillary ependymoma,[938] and clear cell ependymoma[939] variants.

Management. Evaluation of patients at diagnosis or recurrence should include an MRI of the brain and spinal cord, as well as cytologic evaluation of the CSF, usually performed at least 14 days after the operation.[940] Attempting CSF analysis during the surgery or shortly after could give false-positive results. The usefulness of CSF sampling in patients may not be particularly sensitive.[941,942] A number of factors have been associated with an unfavorable outcome, including younger age at diagnosis, subtotal resection, and a high MIB1 labeling index. Anaplastic histology remains controversial as a negative prognostic factor. Of these factors the single most important factor in the determination of prognosis appears to be whether a complete resection can be accomplished.[943]

The first line of treatment is surgery with the goal of GTR. If a complete resection with clear margins of a grade II spinal cord or supratentorial ependymoma can be achieved, adjuvant therapy can be deferred in some patients.[944] Technologic advances such as the operating microscope, Cavitron ultrasonic aspirator, intraoperative ultrasound, and intraoperative MRI, as well as electrophysiologic monitoring, have facilitated the safety of resections of intraaxial spinal cord tumors while reducing operative morbidity.[945] Overall, spinal cord ependymomas are more easily resectable than astrocytomas because of the presence of a better demarcated cleavage plane. Tumors with an infiltrative boundary, or those with anaplastic histology, require adjuvant therapy. All posterior fossa tumors, independent of grade and degree of resection, should also receive adjuvant treatment. Spinal myxopapillary ependymomas with a complete surgical resection have an excellent prognosis[946] and do not usually require adjuvant therapy even in the presence of drop metastases in the thecal sac.[947] Given the overall good prognosis of these tumors, the need for radiation in incompletely resected disease is unclear, and careful surveillance imaging is needed.[948] Early radiation therapy is not always routinely used but is recommended by some persons.[949,950]

Regarding radiation therapy, there is a long history of deferring radiation therapy for infants and young children who have posterior fossa ependymomas, with use of various conventional chemotherapy regimens instead. Previous treatment recommendations included radiation therapy for patients in whom gross resection was not achieved or for patients with recurrent disease. However partially resected tumors almost invariably recur, requiring further surgery, radiotherapy, and conventional chemotherapy. As such, in the United States the current strategy for ependymoma is to recommend deferral of adjuvant therapy in persons with completely resected supratentorial ependymoma, use of radiotherapy in the involved fields alone for completely resected posterior fossa ependymoma, and use of multiagent chemotherapy for subtotally resected ependymoma, followed by second-look surgery and involved field radiation therapy.[951-953] The benefit of hyperfractionation has not been established.[954] Wide-field pulsed reduced dose rate radiotherapy is currently being evaluated.[955] Craniospinal radiation therapy does not appear to be superior to focal radiation therapy.[877] Several studies have suggested that radiotherapy prolongs PFS after subtotal resection of an ependymoma. Deferral of radiation therapy after initial complete resection can result in reduced cure, even when complete resection is achieved a second time.[956] Proton radiation therapy appears to have equal efficacy when compared with photon therapy; it can reduce the potential long-term toxicity by decreasing the volume of normal brain tissue that is also targeted and is therefore recommended over photon therapy if it is available locally.[957,958]

Until recently there was no clear role for chemotherapy in the management of ependymomas outside of clinical trials.[959] Several small series in newly diagnosed and recurrent disease have shown objective responses to the following drugs: carboplatin, cisplatin, ifosfamide, and etoposide.[960] Chemotherapy is more often used for infants and younger children with incompletely resected or disseminated disease.[961-963] Encouraging results have been reported from the most recent cooperative group clinical trial involving preirradiation chemotherapy,[964] which showed a 40% complete response (CR) rate in patients who received preirradiation chemotherapy for residual postoperative tumor.[965,966] The two factors associated with a favorable outcome were the achievement of a complete resection and supratentorial disease. Chemotherapy should therefore be used to achieve a CR or improve the chances of a complete surgical resection at second-look surgery. It is not highly effective as sole treatment for this disease, and recurrences occur relatively rapidly in a significant percentage of patients if radiotherapy is not administered early. Infants may be more responsive, and 23% to 40% can be cured with chemotherapy alone.[967,968] The use of high-dose chemotherapy and stem cell rescue in infants with ependymoma has failed to demonstrate a significant advantage compared with standard modalities in most,[969] although not all, studies.[970] Although uncommon, up to 10% of patients can have leptomeningeal spread of ependymoma. Response to intrathecal liposomal cytarabine has been reported.[961]

Recurrences of intracranial ependymoma can occur throughout the first decade after initial therapy, although most recur within the first few years.[971] Surveillance scanning is important because it allows smaller asymptomatic tumors to be identified that may be more amenable to reresection. Most recurrences are within the original radiation field[972] and do not appear to be related to marginal failures.

Prognosis. The most important prognostic factors for intracranial and spinal cord[973] ependymoma are age, tumor grade,[974] extent of surgical resection, and delivery of radiation therapy with doses of at least 5400 cGy.[975-980] Children younger than 3 years, those with WHO grade III disease, or those with less than a GTR have been shown to have lower survival rates.[981] The 5-year PFS and OS for patients with subtotal versus total resection of posterior fossa ependymomas is 25% and 66%, respectively. The prognosis of patients with disseminated disease is worse.[539,976,982] Patients with a supratentorial nonanaplastic ependymoma can be treated with surgery only if the tumor can be completely resected. Recently a molecular assay for HTERT expression has been shown to predict the likelihood of progression and survival of pediatric intracranial ependymoma.[910] Additional studies on the molecular profile of ependymomas will likely lead to improved stratification and prognostication of patients as previously discussed.[891,912] Patients with an elevated MIB1 labeled index of more than 5% in incompletely resected ependymomas or of more than 15% in completely resected ependymomas were reported to have a worse prognosis in one study.[935] Patients with a deletion of 6q15.3 appear to have an improved outcome.[983] Molecular profiling has identified that the group A ependymomas (posterior fossa, infants) have a more aggressive biologic behavior and worse prognosis when compared with the group B ependymomas (supratentorial),[882] although this classification is not currently being used to guide therapy intensity at the present time.

Most patients with completely resected ependymoma followed by focal radiation therapy will be long-term survivors. Consideration of advanced radiation planning and the type of radiation delivered (i.e., proton vs. photon) are critical to minimize long-term neurocognitive morbidity in this population.[984]

At the time of recurrence, no standard salvage regimen has been proven to be effective.[985] Reoperation to achieve a complete resection has been curative in some patients and is typically the first modality considered[986]; this approach can be combined with reirradiation.[987,988] SRS has also been used with some success for focal recurrences of ependymoma.[989,990] Patients with metastatic disease or infiltration into the brainstem or other critical structures have a poor salvage rate, presumably because of the lack of good therapies for recurrent disease and the inoperable nature of the lesions. Oral etoposide alone[991] or in combination as a metronomic therapy combination has demonstrated responses in this disease.[341,335] Bevacizumab in combination with irinotecan did not show any significant activity.[992] A single case report of a response to the mTOR inhibitor sirolimus has also been published.[993]

Recurrence of myxopapillary ependymoma can occur after complete resection and can be associated with dissemination. Although cranial metastases have been reported, most cases result in regional metastases of the spine but not beyond the foramen magnum.[994] Many of these patients can undergo salvage therapy with radiation. Consequently frequent surveillance scanning of patients with myxopapillary ependymoma is recommended to identify recurrent disease early.

Oligodendrogliomas

Oligodendrogliomas are rare brain tumors in children, representing fewer than 1% of all pediatric brain tumors.[995,996] The mean age at diagnosis is approximately 10 to 13 years, with a male predominance.[997,998] The WHO grading system recognizes two grades for oligodendroglial tumors: well-differentiated grade II oligodendroglioma and grade III anaplastic oligodendroglioma.[999] As with other glial tumors, higher grade is a predictor of decreased OS. Other reported markers in oligodendrogliomas include deletions of the cyclin-dependent kinase inhibitor 2A (*CDKN2A*) gene on chromosome 9p, mutations in *TP53* and *PTEN*, and amplification of the EGFR.[1000,1001] However it is not known whether these factors are predictive of outcome in pediatric patients. Unlike adult tumors, pediatric oligodendrogliomas do not typically have the chromosome 1p or 19q deletions or mutations in *TP53* or *IDH1*.[382]

Clinical Presentation. Oligodendrogliomas are diffusely infiltrating tumors that tend to occur in the white matter of the cerebral hemispheres. Patients frequently present with seizures, although higher-grade tumors may present with evidence of increased ICP because of more rapid growth.[1002] Other symptoms at presentation can include headache, visual field defect, paresis, and cranial nerve palsy.[998] Although uncommon, oligodendrogliomas can also occur throughout other areas of the brain, including the posterior fossa, brainstem, and spine.[1003-1007]

Imaging and Histology. MRI evaluation of oligodendrogliomas typically reveals increased T2-weighted signal and decreased T1-weighted signal.[1002] Gadolinium contrast enhancement is more common in tumors that grow as solid masses and less common in purely infiltrative tumors. Contrast enhancement is also more common in grade III than in grade II oligodendrogliomas.[1008] Although oligodendrogliomas bear morphologic similarity to oligodendrocytes, the cellular origin of these tumors has remained difficult to prove. Histologic examination of fixed specimens of oligodendrogliomas reveals a monotonous pattern of cells with round nuclei and clear perinuclear halos (a "fried egg" appearance). This appearance is an artifact of formalin fixation and is not seen in frozen sections or tumor smears. Higher-grade anaplastic oligodendrogliomas (WHO grade III) are characterized by increased nuclear variability, increased mitotic activity, and/or microvascular proliferation. These features can occur diffusely throughout the tumor or in discrete foci. The differentiation between oligodendrogliomas and other diffuse gliomas such as astrocytomas and OAs is difficult because of a lack of reliable molecular markers that distinguish oligodendroglial tumors from astrocytic tumors. Mature oligodendrocyte-specific markers such as myelin basic protein, 2′3′–cyclic-nucleotide 3′-phosphodiesterase, and myelin-associated glycoprotein are not expressed in oligodendrogliomas, although astrocytic markers such as GFAP and S-100β are expressed in both astrocytomas and oligodendrogliomas.[999] More recently the lineage markers OLIG1 and OLIG2 have been evaluated in the hope that they may enable specific identification of oligodendroglial tumors.[1009] However despite the restriction of OLIG2 expression to normal oligodendrocytes and their precursors, OLIG2 stains all diffuse gliomas and precludes specific immunohistochemical classification of these tumors.[1010] The loss of chromosome 1p and/or 19q is commonly seen in adult oligodendrogliomas and correlates strongly with chemotherapy responsiveness and outcome.[1011] Pediatric oligodendrogliomas have a much lower incidence of chromosomes 1p and/or 19q deletions.[1012,1013] Even in children in whom these deletions are identified, the greater chemoresponsiveness observed in adults is less evident.

Management. Treatment of pediatric oligodendrogliomas, like other glial tumors, involves surgical resection, radiation therapy, and chemotherapy. The goal of surgery is to facilitate accurate diagnosis and to remove as much of the tumor as safely possible. In the adult literature, there is uncertainty as to whether the extent of resection correlates with OS. Although some larger case series have shown no prognostic value in the extent of resection,[1011] most evidence seems to indicate that the extent of resection may be associated with better prognosis.[1014,1015] In pediatric patients, it appears that the extent of resection is a sensitive predictor of outcome.[547] Fewer pediatric low-grade oligodendroglial tumors progress to high-grade tumors, so it is possible that patients with subtotally resected tumors may still have a good outcome. For example in one series of 20 patients with oligodendrogliomas treated with surgery only, 70% remained progression-free at a median of 5 years.[1016]

Despite the fact that oligodendroglial tumors are radiosensitive,[1017] the use of adjuvant radiation therapy in asymptomatic children with incompletely resected oligodendrogliomas is not favored because of the well-described late effects of radiation therapy.[425] Children who are symptomatic, who have tumors in critical locations such as the brainstem, or who have progressive disease despite resection and/or chemotherapy may benefit from radiotherapy.[466] However it is now clear that a subset of these children can be effectively treated with chemotherapy, allowing for a delay in, or avoidance of, radiation therapy.[1018] The combination of carboplatin and vincristine chemotherapy has demonstrated activity in various low-grade astrocytomas, regardless of histologic subtype. This therapy should therefore be considered for patients with oligodendroglioma.[433] Older children may also benefit from chemotherapy.[459] Based on overlapping activity in children with low-grade astrocytomas, the combination of TPCV might also be of use in patients who do not respond to or have disease progression after vincristine and carboplatin therapy. The combination of procarbazine, lomustine, and vincristine or TMZ monotherapy could also be considered based on the responses seen in adults, but these treatments have not yet been adequately tested in children.[492,1019,1020]

In patients with anaplastic oligodendroglioma or progressive disease, despite surgery and adjuvant chemotherapy, the risks of radiation therapy may be offset by the risk of further tumor growth. A recent survey of adult neurooncologists has found that the most commonly recommended treatment for anaplastic oligodendroglioma is the use of concurrent TMZ and radiotherapy followed by adjuvant TMZ.[1021] In rare cases of dissemination, the overall prognosis for these patients is poor, although transient chemotherapy responsiveness can be achieved.[1022] Patients with oligodendroglial gliomatosis cerebri have a very poor prognosis.

Prognosis. Overall long-term survival from low-grade oligodendrogliomas appears comparable with that of other LGGs.[1023] It should be noted, however, that only limited numbers of case series are available, making comparisons among studies difficult. Bowers and colleagues[1016] have reported an OS of at least 5.5 years in a series of 20 patients with low-grade oligodendrogliomas treated initially with surgical resection alone. Six of 20 patients in this series had disease progression at a median of 2.2 years after initial resection. Other studies have reported 5-year OS rates of 65% to 84.4%,[997,998] although the proportion of patients treated with radiation therapy and/or chemotherapy differed among these studies. Children younger than 3 years and children with incompletely resected tumors may do worse.[1024] The rarity of anaplastic oligodendroglioma in children makes specific estimates of survival in pediatric patients difficult. Oligodendrogliomas that are more centrally located do not appear to do as well as those located more peripherally in the cortex.[997]

A number of studies from adult patients have indicated that allelic losses at chromosomes 1p and 19q, typically involving the entire chromosomal arm at both sites, correlate with histologic classification, response to treatment, and prognosis.[1025] Loss at chromosome 1p is a predictor of chemosensitivity, and loss at combined chromosomes 1p and 19q is associated with both chemosensitivity and longer recurrence-free survival.[1026] Recent evidence has indicated that loss at chromosomes 1p and 19q is associated with MGMT promoter methylation and lower expression of MGMT.[1027] Interestingly these chromosomal features appear to be less common in pediatric oligodendrogliomas.[1011,1012] One study has reported the lack of allelic loss in children younger than 9 years, although a modest number of tumors from children older than 9 years had losses of chromosome 1p (45%) and/or 19q (27%).[1013] Nevertheless the incidence of chromosomal losses is significantly less than that seen in adults (50% to 90%). Taken together these studies suggest that the oncogenesis of these tumors is distinct from their adult counterparts.

Oligoastrocytomas

OAs are tumors containing a mixture of two distinct neoplastic cell types that morphologically resemble the tumor cells of oligodendrogliomas and diffuse astrocytomas. These tumors correspond histologically to WHO grade II. The demography of OAs and anaplastic OAs (WHO grade III) is difficult to ascertain because of a high variability in the histopathologic criteria used for classification of these tumors. Clinically these tumors present with signs and symptoms similar to those of astrocytomas and oligodendrogliomas. Tumors arise most frequently in the cerebral hemispheres and lack any neuroradiologic features that would facilitate distinguishing them from oligodendrocytomas. Histologic diagnosis requires the recognition of the two different glial components, both of which must be neoplastic.[1028] Anaplastic OAs are WHO grade III oligoastrocytomas with histologic features of malignancy, including high cellularity, high mitotic activity, and increased nuclear atypia and pleomorphism. Currently treatment for OAs and anaplastic OAs is similar to that for other grade II and III glial lesions—surgical resection with adjuvant chemotherapy and/or radiation therapy for higher grade or progressive lesions.

Embryonal Tumors

Embryonal tumors represent a large and important fraction of pediatric brain tumors, both for their clinical impact and the importance of the scientific insights gained through their study. The most common embryonal tumors include medulloblastoma, pineoblastomas, and CNS PNETs. A number of other tumors are grouped into this category, such as ATRTs, ependymoblastomas, and medulloepitheliomas (see Table 57-6). Recent advances in gene expression array technologies have facilitated a new understanding of the molecular features of tumors within this set of diseases.[1029] The grouping of these tumors into the larger category of CNS PNETs will continue to evolve while a better understanding of their origin progresses. Currently all these tumors share a common property: high risk of dissemination and therefore the need to treat the entire craniospinal axis. It is expected that new technologies will soon allow for a better understanding of the cell of origin of the different tumor types. These considerations are no longer intellectual exercises. Gene-based classification systems may be the key to improved stratification and management and will likely augment, if not replace, the current histopathology-based classification system that underlies current treatment protocols.

The history of small round blue cell tumors is a fascinating story that spans the evolving approach to cancer during the past century. Histopathology was, and remains, the cornerstone of all classification schemas. Tumors from different sites that appeared the same under microscopic examination were assumed to be similar tumors arising from different organs. With the introduction of immunohistochemical techniques of pathologic specimens, pathologists began to define important differences among populations. Small round blue cell tumors within the body were now divided into unique categories based on the presumed cell of origin. Tumors such as lymphoma, neuroblastoma, Ewing sarcoma, rhabdomyosarcoma, and others became easily differentiated. The classification of small round blue cell tumors of the brain, by contrast, took a different direction. Medulloblastoma, a small round blue cell tumor of the cerebellum, was previously differentiated from other similarly appearing tumors based on its location within the posterior fossa,[1030] but some investigators thought that this arbitrary separation was unwarranted. Hart and Earle[1031] attempted to classify all embryonal tumors based on the expanding array of immunohistochemical markers and variations in the patterns of staining among these tumors. Rather than clarifying the classification of embryonal tumors, further blurring of the understanding of these tumors resulted. One contributing factor involved differing definitions for the grouping of embryonal tumors. For some investigators, medulloblastoma was considered a PNET and thus was lumped with pineoblastomas and sPNETs, whereas for other investigators, medulloblastoma remained a separate category. Another factor was the considerable variability in the quality of the staining pattern and heterogeneity within different areas of a single tumor and within different tumors of the same type. With advances in molecular pathology, classification has moved away from the simple microscopic appearance of a tumor to one that incorporates the pathways active in the tumor. Molecular signatures for these different tumors have been demonstrated; these signatures have shown that the tumors arise from different cell populations and, as a result, these tumors will likely require different treatments. Many prior treatment protocols grouped all these heterogeneous tumors together, which has confounded the true efficacy of the therapy under consideration and the prognoses for this heterogeneous group of tumors.

TABLE 57-6 Classification of Embryonal Tumors

Tumor Location	Histologic Classification	Histologic Subtype
Fourth ventricle	Medulloblastoma	Classic or nondesmoplastic Desmoplastic Anaplastic Large cell Melanotic
	Cerebellar neuroblastoma* Atypical teratoid-rhabdoid tumor	
Pineal	Pineocytoma Pineoblastoma Atypical teratoid-rhabdoid tumor	
Supratentorial or intratentorial	Primitive neuroectodermal tumor* Cerebral neuroblastoma Atypical teratoid-rhabdoid tumor Ependymoblastoma†	

*The nomenclature for neuroblastoma and primitive neuroectodermal tumor (PNET) in the central nervous system results from the historic grouping of these tumors with other small round blue cell tumors of the body. Primary cerebral or cerebellar neuroblastoma are unrelated to similarly named tumors in the body and do not possess the abnormalities in the N-Myc pathway. Similarly central nervous system PNET is unrelated to Ewing sarcoma PNET and does not possess the classic chromosome 11;22 translocation.

†Ependymoblastomas were previously grouped with ependymomas but are now differentiated from this group as a result of their embryologic development and patterns of spread.

Medulloblastomas

Medulloblastomas represent approximately 15% of all pediatric brain tumors and approximately one third of posterior fossa tumors.[1032,1033] In addition medulloblastoma accounts for more than 50% of pediatric embryonal intracranial tumors. The incidence in males is twice that of females, and the median age at diagnosis is 5 to 7 years, with most cases diagnosed in the first decade of life.[1034] The current standard of care for children diagnosed with medulloblastoma involves maximal surgical resection and adjuvant therapy with radiotherapy and chemotherapy. Radiation therapy involves a boost to the tumor site with craniospinal prophylaxis. Chemotherapy is administered both concurrently with radiation therapy and as multiagent maintenance chemotherapy after the completion of radiation therapy. Approximately 80% of children with medulloblastoma are cured,[1035] but current treatment strategies result in significant long-term morbidity.

With recent advances in transcriptome and genomic profiling of medulloblastoma, it has become apparent that medulloblastoma encompasses a heterogenous group of tumors with distinct pathologic features and clinical outcomes.[1036-1039] These findings represent exciting prospects for the development of novel tumor-directed therapies and treatment strategies that are stratified according to the genetic profiles of the individual medulloblastoma.

Different subtypes of medulloblastoma are thought to originate from distinct germinal zones within the cerebellum—the EGL, which contains committed granule cell precursors, and the ventricular zone, which contains multipotent stem cells that give rise to most cerebellar neurons. Several cancer predisposition syndromes carry an increased risk of medulloblastoma, including nevoid basal cell carcinoma syndrome or Gorlin syndrome, Turcot syndrome, and Li-Fraumeni syndrome.[1040-1042] Gorlin syndrome, although rare, is an important factor that must be considered in the treatment of these patients, because they are at high risk for the development of nevoid basal cell carcinoma, especially within the involved radiation fields.[1043] In addition Gorlin syndrome provided the first clues as to potential pathways that may be involved in the pathogenesis of medulloblastoma, with the finding of mutations in SHH pathway members, such as *PTCH1*, increase the risk of tumorigenesis.[1044]

Recent cooperative studies have comprehensively profiled the biology of medulloblastoma to reveal four distinct subgroups of tumors.[1036-1039] The groups are distinguishable from each other on the basis of gene expression, methylation, copy number, and mutation profiles.[1045-1049] These groups have been designated as Wnt-positive medulloblastoma, SHH-positive medulloblastoma, and group 3 and group 4 medulloblastoma.[1037] Wnt-positive medulloblastomas are characterized by mutations of β-catenin, resulting in activation of Wnt pathway signaling. Children with Wnt-positive medulloblastoma rarely have metastatic disease and have an excellent overall prognosis. The SHH group is characterized by tumors that carry mutations of the SHH pathway, with resultant pathway activation. The types of SHH pathway mutations differ between infants, children, and adults and may affect the use of targeted therapies for this group.[1050] These tumors can encompass multiple histologic subtypes, although nodular desmoplastic medulloblastomas are more likely to carry SHH pathway mutations. Group 3 medulloblastomas carry a poor prognosis and are largely characterized by amplification of *MYC* or amplification/overexpression of the *OTX2* oncogene. Group 4 medulloblastomas carry an intermediate prognosis and are likely to have isochrome of 17q, and gene expression studies show enrichment of genes involved in neuronal differentiation and development. *TP53* mutations have been described to be enriched in the SHH subgroup of medulloblastoma, and when present, they are associated with inferior responses to therapy.[1051] Profiling studies of recurrent medulloblastomas have revealed that the subgroup determinations are stable, with recurrent tumors maintaining the same subgroup profile as they were at diagnosis.[1052]

In addition to the driver genomic alterations identified in medulloblastoma, evidence is growing that epigenetic dysregulation may play a role in the pathogenesis of these tumors.[1045] This belief is supported by the observation of enrichment in genomic alterations of chromatin modifiers in large-scale profiling projects for medulloblastoma.[1049,1053,1054] These alterations include inactivating mutations of the histone methyltransferase genes MLL2 and MLL3,[1055] *KDM1A* a histone demethylase[1056] and *SMARCA4*, a member of the SWI/SNF chromatin remodeling complex.[1053,1057] Mutations and aberrant hypermethylation of the telomerase reverse transcriptase (TERT) promoter have also been recently described in large-scale sequencing projects of medulloblastoma.[1058] Mutations in TERT promoters have been found to be particularly enriched in the SHH subtype of medulloblastoma.[1059] In addition altered expression of genes regulated by the polycomb repressor complex have also been described in medulloblastoma.[1060,1061] Alterations in chromatin modifiers have been described in medulloblastoma, and novel agents that target chromatin modification are being investigated as potential therapeutic for medulloblastoma. These agents include drugs that suppress expression of the MYC isoforms by inhibiting bromodomain containing 4 (BRD4), a bromodomain and extraterminal (BET)–containing protein,[1062] and inhibitors of enhancer of zeste 2 (EZH2).[1060]

Alterations in genes involved in cell cycle regulation have also been described in medulloblastoma.[1049] These alterations include amplification of cyclin-dependent kinase (CDK)/cyclin D genes[1063] and loss of the cell cycle inhibitor p27Kip1.[1063] Inhibition of *CDK6* has been shown to reduce cell proliferation in medulloblastoma cell lines,[1059] and small molecule CDK inhibitors may have a potential therapeutic role in this disease. In addition strategies that target G2-M regulators have also been investigated in model systems of SHH medulloblastoma using Aurora and Polo-like kinase inhibitors.[1064,1065]

No specific single environmental factor has been demonstrated to be associated with the development of medulloblastoma, although the nonrandom occurrence of disease detected in children born in the fall raises the possibility that some environmental or infectious pathogen may be implicated.[47] The association between the development of medulloblastoma and viruses remains controversial. Multiple reports implicating polyomaviruses (including JC[1066] and SV40[1067,1068] virus in animal models) as a causative agent in medulloblastoma have been published. Human medulloblastoma samples have been found to possess JC and SV40 viral sequences.[918,1069,1070] However independent confirmation of JC and SV40 sequences in human tumors could not be duplicated.[51,920] Prematurity was identified as a significant risk factor in one study.[1071] Whites are affected 42% more often than blacks.[1072] In contrast several genetic syndromes (e.g., nevoid basal cell carcinoma syndrome or Gorlin syndrome, Turcot syndrome, and Li-Fraumeni syndrome) are associated with a significantly increased risk for the development of medulloblastoma.[1040-1042] Gorlin syndrome, although rare, is an important factor that must be considered in the treatment of these patients, because they are at high risk for the development of nevoid basal cell carcinoma, especially within the involved radiation fields. Children of African-American descent require especially careful skin evaluation for the early detection of these lesions.[1043]

Clinical Presentation

Many of the clinical manifestations of medulloblastoma are similar to those of other tumors that arise in the fourth ventricular region and are related to obstructive hydrocephalus. Headache, nausea, and vomiting, characteristically in the morning, are the most common initial symptoms and usually precede diagnosis by 4 to 8 weeks, although longer intervals are not uncommon, especially if the headaches and vomiting caused by obstructive hydrocephalus are intermittent.[1073] Interestingly it appears that the duration of presenting symptoms may correlate inversely with disease state at the time of presentation; patients with low-stage disease were shown in one series to have a longer median duration of symptoms than were patients with high-stage disease.[1074-1076] Personality changes (irritability) are an early feature but may be difficult to recognize as a sign of a brain tumor. Other features that can lead to diagnosis include lethargy, diplopia, head tilt, and truncal ataxia. The common signs found on physical examination are papilledema, ataxia, dysmetria, and cranial nerve involvement. Abducens nerve (cranial nerve VI) palsy as a result of raised ICP may cause diplopia and head tilt. Torticollis can be a sign of cerebellar tonsil herniation. Less commonly, intratumoral hemorrhage may lead to acute onset of confusion, headache, and loss of consciousness. The presentation in infants may include an abnormal rate of increase in head circumference. Other presenting symptoms can include loss of previously achieved milestones and failure to thrive. With regard to metastatic disease, at the time of diagnosis, although lumbar CSF analysis or MRI-visualized leptomeningeal metastases occur in 20% to 30% of children with medulloblastoma,[1077,1078] clinical manifestations of metastases are uncommon. Back pain and radicular pain may indicate the rare complication of spinal canal dissemination. Attention to the clinical manifestation of posterior fossa tumors is important because the presenting signs mimic many other common ailments in children, including viral infections and stress. Because tumors have a significant propensity to metastasize early, careful evaluation of associated neurologic signs (e.g., papilledema and diplopia) can help identify children in need of referral for imaging sooner.

Imaging and Histology

Most medulloblastomas arise in the cerebellar vermis and extend into the fourth ventricle, resulting in obstructive hydrocephalus. The remainder are localized to the cerebellar hemisphere, especially in older patients and those with the desmoplastic subtype.[1079] The signs and symptoms of obstructive hydrocephalus, such as severe headache, morning vomiting, long tract signs, and papilledema, can be a medical emergency and require immediate evaluation. CT scanning of the head or rapid sequence MRI is the immediate choice of imaging to rule out an obstructive mass. This rapid study provides good differentiation between the fluid cavities and brain and will be sufficient to allow the neurosurgeon to determine whether immediate action is required. Often CSF diversion can be avoided if tumor resection is immediately possible. When required third ventriculostomy is preferred to VP shunts. All patients will require high-quality MRI scans of the brain and spine, including the entire thecal sac at the base of the spine. Lumbar puncture for CSF cytologic examination in newly diagnosed patients should be deferred if any possibility of elevated ICP exists; lumbar puncture is usually better performed after the tumor has been resected and CSF flow has been restored.

The MRI findings may differentiate between medulloblastoma types,[1080] as well as from other cerebellar tumors, such as ependymoma and pilocytic astrocytoma, and may be helpful before surgical resection.[1081] However atypical appearances of these three tumors can also occur, and thus a diagnosis based solely on imaging characteristics currently is not feasible. The appearance of a vermian location, hypercellularity (often demonstrated as dark areas of tumor on T2-weighted imaging), and intratumoral hemorrhage is more compatible with a cellular medulloblastoma or an ependymoma. A tumor that fills the fourth ventricle and extends through the foramina of Luschka and Magendie is more likely to be an ependymoma, although one with a large cyst and mural nodule (with a small area of solid tumor) is more consistent with a PA. PAs typically arise in the cerebellar hemisphere and are imaged on T2-weighted MRI as areas of homogeneous high-signal intensity, with the fluid collections defining the less intense tissue components of the tumor.

Medulloblastoma has T1-weighted MRI signal characteristics more similar to those of gray matter, reflecting hypercellularity and typically resulting in a relatively homogeneous image. On T2-weighted images these tumors can appear to be hyperintense or, more frequently, they can display mixed signal characteristics indicative of small intratumoral cysts, calcification, or small areas of hemorrhage.[1082,1083] The background signal intensity of medulloblastoma on T2-weighted images is characteristically lower than in other tumor types, indicating a dense packing of cells and a high nuclear-to-cytoplasmic ratio. Because medulloblastoma typically arises in the roof of the fourth ventricle, a cleft of CSF beneath the tumor in the fourth ventricle helps distinguish this tumor from ependymoma. Tumors are typically enhanced with administration of gadolinium (Fig. 57-36). The presence of characteristic gyriform morphology and a well-circumscribed appearance on an MRI scan suggest the presence of the nodular subtype of medulloblastoma.[1084] Functional imaging with PET and SPECT are helpful for the improved diagnosis of medulloblastoma. A number

An area of hemorrhage is present. **B,** A sagittal T1-weighted image with contrast of a medulloblastoma. **C,** An axial T2-weighted image. The areas of low T2 signal suggest a cellular lesion. **D,** A saggital T1-weighted image with use of contrast material. The lumbar-sacral-enhancing nodules *(arrows on left)* and leptomeningeal coating *(arrow on right)* represent metastatic disease.

of agents such as oxidronate (OctreoScan) can directly assess for the presence and activity of certain cellular constituents, which helps differentiate recurrent disease from scarring.[1085]

Histopathologic analysis of resected tumor specimens is essential for diagnosis and treatment planning. It should be noted that the histopathologic classification and nomenclature of medulloblastoma, within the broader context of embryonal tumors, has long been controversial and even today shows signs of continued evolution.[1086] The most current WHO classification schema considers medulloblastoma to be an independent entity in the group of embryonal tumors,[1040] separate from sPNET (now called CNS PNET in the revised WHO classification[207]). Within medulloblastoma, it is also clear that these tumors are not a homogeneous entity from a histopathologic viewpoint. At present five main histologic subtypes are recognized—classic, desmoplastic-nodular, anaplastic, large cell, and medulloblastoma with extensive nodularity. In addition any of these five variants of medulloblastoma can have areas of myogenic or melanotic differentiation.[1087] Classic (nondesmoplastic) medulloblastoma is the most common subtype, with approximately two thirds of tumors being classified as such, followed by the desmoplastic subtype (25%). This distribution is not uniform and is influenced by factors such as age and the presence of Gorlin syndrome. Individual tumors are often heterogeneous with regard to the extent of desmoplasia.[1088,1089]

Classic medulloblastoma consists of uniform sheets of densely packed small round blue cells with round to oval hyperchromatic nuclei and scant cytoplasm[1040] (Fig. 57-37). Desmoplastic medulloblastoma is characterized by so-called pale islands, or reticulin-free nodules, that are surrounded by reticulin-producing proliferating cells. Desmoplastic medulloblastoma is linked to the

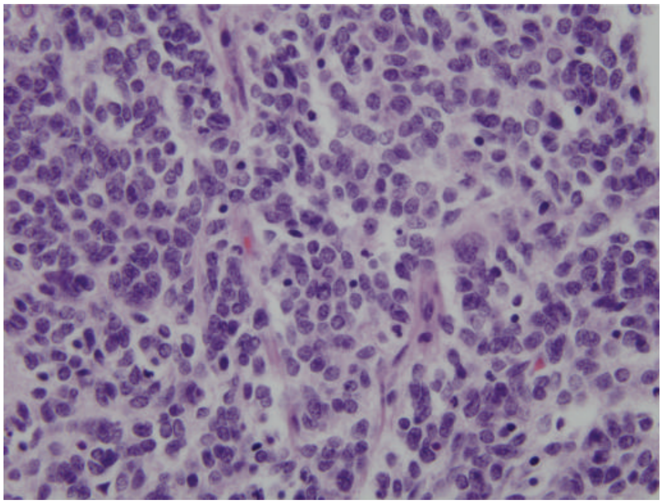

Figure 57-37 Nonanaplastic medulloblastoma. Lesions consist of sheets of homogeneous-appearing undifferentiated tumor cells (hematoxylin and eosin; ×600).

nevoid basal cell carcinoma (Gorlin) syndrome, caused by mutations in the *PTCH1* gene and leading to dysregulation of SHH signaling. Only recently have the large-cell and anaplastic variants of medulloblastoma been identified. These variants are defined by light microscopic findings of prominent nuclei with a high degree of pleomorphism, high mitotic indices, increased cytoplasm, and a higher rate of necrosis than in other variants.[1090] These tumors are uniformly positive for synaptophysin and are generally positive for chromogranin. Anaplastic and large-cell medulloblastomas tend to have higher rates of metastasis at presentation, loss of chromosome 17p13.3, and *MYC* amplification, and both have relatively poor prognoses.[1091] These two variants can occur together and contain cells with markedly increased nuclear atypia and/or large nuclei with prominent nucleoli (Fig. 57-38).[1091-1093]

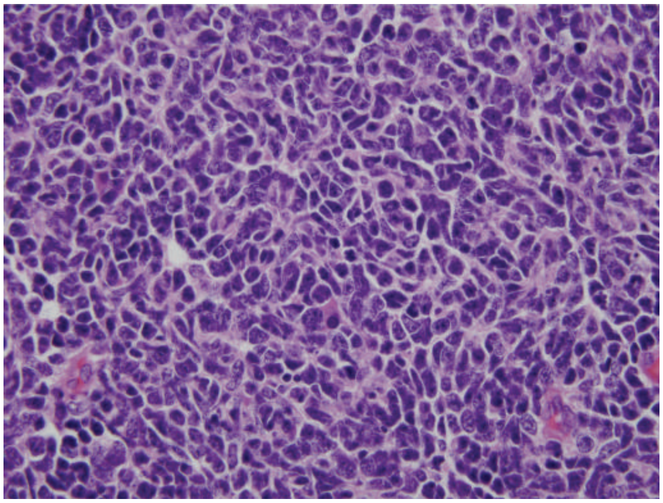

Figure 57-38 Anaplastic medulloblastoma. Tumor cells are pleomorphic with atypia, increased nuclear size, nuclear molding, and cell-cell wrapping (hematoxylin and eosin; ×600).

Wnt-positive medulloblastomas are usually classic histology. SHH group tumors include classic histology tumors, and nodular desmoplastic medulloblastomas most commonly belong in this group. Group 3 and 4 tumors have higher rates of MYC or MYCN amplification and isochrome 17q.

One of the cardinal features of medulloblastoma is its tendency to differentiate along one or more pathways, most commonly neuronal, astrocytic, and ependymal lineages. Synaptophysin expression, a characteristic feature of medulloblastomas, indicates neuronal lineage.[1094] The expression of certain intermediate filament proteins, such as nestin, vimentin, and GFAP, can also be seen in medulloblastomas.[1095] Medulloblastoma is divided into five variants:

1. Nondesmoplastic (classic) medulloblastoma may be strongly immunoreactive for vimentin. Although GFAP expression is typically restricted to developing and mature astrocytes, most classic medulloblastomas contain GFAP-positive cells, which could indicate astrocytic differentiation.[1040]
2. Nodular-desmoplastic medulloblastoma has been shown to have an increased degree of reticulin staining,[1096] with reticulin-free areas that can be identified throughout the lesion or only focally. The nodules represent regions of neuronal maturation.[1040] This rare subtype makes up only 5% of medulloblastomas but accounts for 57% of medulloblastomas in infants[1089] and accounts for the particularly good outcome in this age group.[1097]
3. Anaplastic medulloblastoma has marked nuclear pleomorphism, a high mitotic rate, apoptotic cells, and significant atypia. If only small areas of anaplasia are identified, the tumor does not meet the diagnostic criteria for the anaplastic subtype. Experienced pediatric neuropathologists are therefore required for difficult cases. Anaplasia may be related to abnormalities in *c-Myc*.[1098,1099]
4. Large-cell medulloblastoma is a rare subtype with abundant mitoses and apoptotic bodies.[1093] The name derives from the large nuclei that are present.[1100] It often contains areas of anaplasia, possibly related to specific aberrant signaling pathways,[1101] and thus many refer to these two variants as large-cell/anaplastic medulloblastoma.
5. Medulloblastoma with extensive nodularity, previously called cerebellar neuroblastoma, is typically identified in infants and has very large reticulin-free zones in comparison with desmoplastic medulloblastoma.[1102]

Medulloblastoma with myogenic differentiation refers to the presence of rhabdomyoblastic elements[1103,1104] and can be seen with any of the five variants of medulloblastoma discussed earlier (classic, desmoplastic, anaplastic, large cell, and medulloblastoma with extensive nodularity).[1105] The historic term for medulloblastoma with rhabdomyoblastic elements was *medullomyoblastoma*,[1106] although this latter term is no longer recommended. Similarly medulloblastoma with melanotic differentiation refers to the presence of melanin and does not represent an additional unique variant of the disease.[1107,1108] Rather

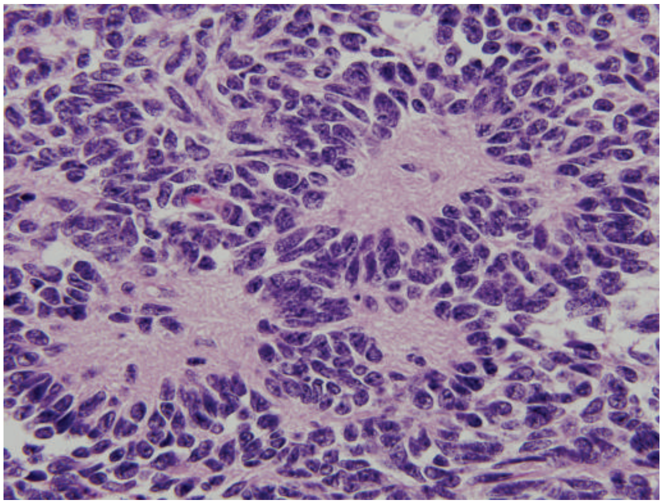

Figure 57-39 Homer-Wright rosettes (hematoxylin and eosin; ×600).

melanotic differentiation can occur with the other recognized variants. This tumor type was previously called “melanocytic medulloblastoma.”

Mitoses and other markers of proliferation such as the MIB1 labeling index are common features of these tumors and do not alter the prognosis.[1109] A mitotic index of 0.5% to 2%, an MIB1 index higher than 20%, and the presence of Homer-Wright rosettes, that is, cells arranged around a central lumen or hub (Fig. 57-39),[1110] are often associated with increased atypia and mitotic activity and are seen in approximately one third of cases. Pseudorosettes—that is, cells arranged around a central clearing with a vessel in the middle—are a common feature of medulloblastoma but are variable; they are not prognostic. Vascular proliferation and necrosis are uncommon.

Determining the cellular origin of medulloblastoma may be a key to the proper stratification and management of these tumors.[1111] As noted earlier current evidence indicates that patients with the desmoplastic variant, which is thought to originate from cerebellar granule cell precursors, have a better prognosis than patients with the classic or large-cell/anaplastic variants.[1112] Similarly patients with the large-cell and anaplastic variants appear to have a worse prognosis, and our developing understanding of the unique pathways involved will likely allow better classification and therapy in future studies.

Historic Perspective

Like most other treatments, the development of our current approaches to multimodality therapy for medulloblastoma is the result of a series of overlapping clinical trials. It is beyond the scope of this chapter to give a detailed recounting of the progression to our current understanding of medulloblastoma therapy. Rather a few key events will provide some idea of why we do what we currently do and indicate some of the weaknesses on which our current assumptions are based.
